BLOOD AND IRON.

Plant Disease and its Relation to Animal Life. By E. F. Wright. Pp. vi + 160. (London: Swan Sonnenschein and Co., Ltd., 1903.) Price 3*s*. 6*d*.

THIS little book with so alluring a title is emphatically disappointing, and would appear to have been written by a compiler quite inadequately informed on the subject, especially in its botanical aspect.

The principal contention of the author seems to be that, because iron is necessary for the production of chlorophyll in the green plant, and is an indispensable ingredient in relation to the hæmoglobin of the blood in animals, these two bodies, chlorophyll and hæmoglobin, are the same. Thus on p. 1 we read, "Now what chlorophyll is to the plant, hæmoglobin is to the animal, the one being a red modification of the other," and, p. 69, "As hæmoglobin is allied to the proteids and a red modification of chlorophyll, it follows that the hæmoglobin of the animal varies as the chlorophyll or chlorophyll products vary in the plants eaten."

He then proceeds to argue that if an animal eats plants deficient in chlorophyll (*i.e.* chlorotic) it suffers the evils due to want of iron—*e.g.* (on p. 6) "animals eating chlorotic food must be deficient in sugar, fats and proteids," which would seem to indicate (since the author appears not to discriminate between chlorosis and etiolation) that people who are fond of cauliflowers, asparagus, endive, rhubarb, and the like, run risks hitherto unsuspected. For note this (p. 13), "if my contention is correct, the susceptibility to certain bacterial diseases is directly traceable to the use of chlorotic food." And on p. 15, "from which it follows that a chlorotic plant will contain less proteids than a plant containing the maximum quantity of iron." And, again, p. 28, "it is clear that there must be a large number of animals living entirely or partly on this chlorotic vegetable food, from which it follows that a large portion of animal life must be more or less anæmic through eating this chlorotic food."

We have already stated that the author draws no distinctions between different forms of chlorosis and etiolation, and puts the former down simply to a lack of iron. Now let us see what he regards as the measure of this deficiency, bearing in mind that modern plant physiology teaches us that the traces of iron found necessary to develop the peculiar form of chlorosis in question are so minute that it is often somewhat difficult to ensure the absence of that element in experimental cultures.

On p. 7 we read, "Yet there are many soils quite wanting in iron, and in the history of agriculture you never read of manuring with iron, excepting possibly in the case of some experimental plots, although some iron has been used of late years in the form of basic slag, which contains about 18 per cent. of iron," and, further on the same page, "Unfortunately, much vegetation is deficient in iron, and consequently chlorotic, and it would seem simpler instead of washing with sulphate of iron, as is now occasionally done, to have recourse to manuring the ground with iron," all of which goes to show that the author's notions as to the relations between iron and plants are, to say the least of it, crude. Does he seriously suppose that basic slag is used as manure on account of the iron it contains?

But lest there should be any risk of misunderstanding the author's meaning here, we may quote the following from this amusing book. After describing how one lamb of a flock, too weak to proceed, was rescued and brought up by the children of a blacksmith, the author continues (p. 34), "This lamb grew up by grazing on the grass growing round this [the blacksmith's] shop, and was shorn three times in three years," &c., and he explains the excellent condition of this lamb as follows:—"In the first place, it is quite certain there would be plenty of iron in the soil for some distance round a country blacksmith's shop, owing to rusty iron being carried about, to say nothing of the scales of iron and iron filings," &c.

To show what gourmands for iron the author's animals are, we quote from p. 93:—"And to show that

animals require iron, I have seen mules licking rusty iron, just as thousands of people have seen horses licking salt," to which valuable testimony he quotes an account of quails in Florida picking at the holes in the steel rails.

But to appreciate fully what a man of blood and iron we are concerned with, it is necessary to obtain some insight into his views of what his plants and animals do with these relatively enormous quantities of the metal.

We read on p. 5, "iron is the means of fixing the ammonia of the air in the soil to form nitrates. In any case I am sure there is a fixed law by which the ammonia of the air is fixed in the soil to form nitrates . . . ." Then, on p. 21, "it has been proved over and over again that iron is fatal to all fungi, consequently it is unreasonable to suggest that bacteria would attack a perfectly healthy animal, and destroy the blood containing a constituent which was a poison to them."

And, again, on pp. 98–99, "The distinct chemical difference between fungi and what we look upon as ordinary plants, is that the fungi contain no iron or nitrogen, while these constituents are essential to ordinary plant life. It is known that iron and nitrogen are fatal to fungi, therefore the more iron and nitrogen animal life takes up in its food the more likely it is to be immune to bacterial diseases."

It might not unreasonably be expected that we had here plumbed the depths, but the following shows that there are nether regions still, for on p. 42 we have the astounding statement, "It is fully recognised that iron and nitrogen in combination with the phosphates are the means by which the plant is enabled to take up the carbon of the air, . . ." and on p. 68, "it is admitted that the proteids are fatal to pathogenic bacteria." Even these are not the only contributions of the author to the study of bacteria, for he states (p. 98) "it is recognised that all classes of bacteria can only live on foods corresponding in chemical composition to themselves," which pronouncement would appear to require some explanation in view of the previous one regarding proteids, for instance, and the following, quoted from p. 33:—"it is admitted that pathogenic bacteria cannot live in the presence of proteids."

What the author's idea of a proteid may be we have been unable to make out, but there is no hesitation needed in regard to some of his notions regarding immunity, of which the following is a specimen (p. 60):—"Another important factor in immunity is electricity, which is so closely connected with the chemistry of the animal that it is reasonable to think that an animal of normal chemical combination will be in a position to produce much more electricity than an animal chemically deficient."

Immunity is a fascinating but a very difficult subject, but the author is not deterred by the latter in his submission to the former attribute.

On pp. 118–119 we read, "although Storer does speak of the better kinds of humus, yet it may be a chlorotic humus, or it may be a humus containing a maximum chlorophyll, or any variation between the two, which variation would be capable of constituting a great chemical difference." Indeed, we should think it would! But let us read on (p. 120), "if you have a field rich in all the essential mineral constituents, in an assimilable form, and a green crop be grown in this field and ploughed in, and then a cereal crop be grown, this cereal crop will be immune to rust, to say nothing of other parasitical diseases." Here it might be said that the author is merely claiming that high manuring renders a crop more immune, did not the context show that his ideas are by no means so simple, and if the continuation on p. 120 were overlooked, "while if in another field, very deficient in these assimilable mineral constituents, a green crop was grown of a chlorotic nature and ploughed in, then the cereal crop grown would not be immune owing to the imperfect chemical functions performed by what I may call a chlorotic humus."

And this, after all the careful work that has been done on the cereal rusts and other parasitic diseases!

On p. 131 the author declares that "parasitic fungi and bacteria can only flourish when the plant (or animal) on which they feed is deficient in chlorophyll or chlorophyll matter, or their products."

An interesting specimen of the author's quality appears in the following naïve passage on p. 148:—"Slugs, indeed, living as they do like the fungi mainly upon decaying vegetable matter, are not unlike creeping fungi, and I believe it can be shown that they are chemically of a similar composition." Again, p. 158:—"I have now pointed out that there are forms of insect life that are to all intents and purposes simply an extension of the fungi."

These suggestive quotations will, we are of opinion, convince the reader that the present volume cannot be said to be of any use to a serious student of science.

MINES AND MINERALS OF THE UNITED STATES.

Mineral Resources of the United States. Calendar Year 1901. Pp. 973 and index. (Washington: Government Printing Office, 1902.)

THIS is the eighteenth volume of the well-known series issued by the United States Geological Survey, and, like those which have gone before, it is full of valuable information concerning the mineral output not only of the country itself, but also of the world generally. The book consists of a number of articles written by various experts; thus the production of iron ore is dealt with by Mr. Birkinbine, and the American iron trade by Mr. Swank. Mr. G. F. Kunz contributes some interesting pages upon precious stones, whilst the coal trade is reviewed by Mr. E. W. Parker. The consequence is that a more useful contribution to knowledge is made by the United States Geological Survey than by the British Home Office in its annual mineral statistics.

The introductory remarks written by Dr. David T. Day tell us that the total value of the minerals produced in 1901 is reckoned at 1,086,529,521 dollars, or about 223 millions sterling; this is more than twice the value of the mineral output of the United Kingdom last year. It must be pointed out, however, that the

American figures are swollen by taking the value of the metals and not the value of the ores, but even if the comparison with this country were made upon strictly identical lines, we should still be a long way behind.

In 1901 the United States produced more coal, copper, gold, iron, lead, salt and silver than any other country in the world. The yield of coal was about one-third of the world's supply. This mineral is mined in twenty-eight different States, Pennsylvania being, of course, by far the most important. Twenty-four States are producing iron ore, Minnesota heading the list with 11 million tons of red hæmatite.

Montana yields about two-fifths of the copper of the United States, the Lake Superior district about one-quarter, and Arizona about one-fifth.

Colorado has outstripped California, and is now the leading gold-producing State.

Mr. Oliphant's chapter upon natural gas is sure to claim much attention, and is of special import for those who are interested in our new supply in Sussex. The advantages of this cheap and economical fuel are lauded to the skies by the author, who reckons that the quantity tapped and supplied in 1901 exceeded one cubic mile in volume; 21,848 miles of mains, 2 to 36 inches in diameter, are employed in distributing the gas to consumers.

We learn from Mr. Struthers that the United States are the largest producers of borates in the world. Most of the borax is obtained by treating the colemanite of California.

According to Mr. Joseph Hyde Pratt, who deals with abrasives, artificial corundum is now being employed in the manufacture of emery wheels. It appears that bauxite is converted into corundum by means of great heat and pressure in an electrical furnace. The mineral monazite is far more widely distributed than was imagined when its name was chosen in allusion to its supposed rare occurrence; it derives its commercial value from the small percentage of thoria which it contains. The quantity washed from gravels and sands in North and South Carolina in 1901 amounted to 334 tons.

In dealing with a great work like the volume under review, it may seem ungenerous to point out a small and trifling error, but probably Mr. Birkinbine will be glad to correct the statement that "no true manganese ore is won" in Great Britain. The Merionethshire ore cannot be fairly described as "manganiferous iron ore" when an analysis[1] shows 25 per cent. of manganese and only 4 per cent. of iron.

[1] Halse, "On the Occurrense of Manganese Ore in the Cambrian Rocks of Merionethshire." (*Proc.* N.E. Inst. M. and M. Eng., vol. xxxvi. 1887).

CLIMATOLOGY.

Handbook of Climatology. Part i. General Climatology. By Dr. Julius Hann. Translated by Robert de Courcy Ward. Pp. xv + 437. (London: Macmillan and Co., Ltd., 1903.) Price 12*s*. 6*d*. net.

THE translation into English of the first volume of Dr. Hann's "Climatologie" is a very welcome addition to the library of English-speaking meteorologists. The translation does not extend to the last two volumes of the original work, which deal with special climatology, as it has been found "impracticable" to translate them. This is greatly to be regretted, for the generalisations which constitute the science of climatology cannot be satisfactorily treated without reference to the statistical data and the means for verifying them. Moreover, a compendious review, in English, of the statistics of the various meteorological elements arranged according to geographical distribution is constantly wanted for many purposes, and either a translation of Dr. Hann's volumes, or a reproduction in an abridged form of Dr. Buchan's volume of the *Challenger* reports, is a necessity of which every student of meteorology must be aware. It is quite true that such a survey would be a work of reference, and would not serve as a text-book in a course of general climatology, and as that is Prof. Ward's purpose in preparing the translation, we must unfortunately wait for some other interest to prompt the translation of the two volumes of special climatology.

The translator himself explains the relation of the English version to Hann's first volume:—

"This translation, as it stands, essentially reproduces the original. Numerous references, especially such as will be most useful to English and American students, have been added, and changes have been made in the text in order to bring the discussion down to date. A natural temptation to expand the original has been yielded to in very few cases only. Practically all of the important publications which have been issued since the completion of the second German edition are referred to. Some new examples of different climatic phenomena have been added, chiefly from the United States. Most of the examples given, however, necessarily still relate to Europe, because the climatology of that continent has been studied more critically than that of any other region. A few cuts have been made where the discussion concerned matters of special interest to European students only."

Among recent works, references to which have been incorporated, Bartholomew's "Atlas" is conspicuous, but the remarkable Russian "Climatological Atlas," published in 1900, is not, although it furnishes a large number of illustrations of climatological principles.

A distinction is drawn by Hann between climatology and meteorology, but when one deals with general climatology it is rather hard to maintain the distinction. In dealing with the analysis of climates into solar, or mathematical climate, and physical climate, with such subdivisions as mountain climate, continental and marine climates, forest climate, and such supplements as mountains as climatic barriers, geological changes of climate and periodic variations of climate, all of which are treated in the book, it is obvious that neither author nor translator would be content with the mere analysis of figures representing these different sections. The mode of classification at once suggests the causes of climate, and the investigation of such causes is practically general meteorology.

It is scarcely necessary to refer to the admirable way in which Dr. Hann arranged his introductory volume to include a survey of all the general facts about climate and its local variations, and to produce a book

which always surprises those who take it up by the fulness of its information and by the interest which it stimulates. There is no specific indication in the present volume as to what parts are derived from the original and what parts are due to Prof. Ward's careful editing; in any case, the result of the collaboration is a most admirable book.

W. N. Shaw.

OUR BOOK SHELF.

The Steam Turbine. By Robert M. Neilson. Second Edition. Pp. xvii + 294. (London: Longmans, Green and Co.) Price 10*s.* 6*d.* net.

The history of the steam turbine previous to the reign of Parsons, whose first patents were applied for in 1884, may be made out from chapters i. and ii. But descriptions of inventions in the language and with the illustrations usual in patent specifications are not quite what is expected from the author of such a book as this. There is an appendix giving the names and dates of all patents relating to steam turbines. The history and construction of the Parsons and the Laval turbines are given at some length, with the results of practical tests for power and consumption of steam, and the reader gets an opportunity of understanding the construction of modified forms which are now, under various names, coming into use. Students are anxious to examine good drawings and descriptions of the details of the Parsons turbine, and it would appear that these are difficult to obtain. The author of this book has given much information and many illustrations somewhat in the style made familiar to us in the engineering newspapers. Much more information is given about the Laval type of turbine. As to the theory of these turbines, the essentially important points seem to be ignored, and yet all the theory of any turbine known to anybody may be given very shortly indeed. There is a particularly interesting point in connection with the Laval turbine to which the author might have directed attention, namely, the exceedingly great speed reached by fluid at the end of an expanding mouthpiece. So far as we know, the reason for this has never been published, and yet any student of the papers of Osborne Reynolds ought to be able to give it readily.

The chapter on the propulsion of ships by turbines is interesting.

On the whole, the book is one that ought to be read by students; it is practically the only book on the subject, but we think that the author has not done so well with his materials as he might have done.

Whittaker's Electrical Engineer's Pocket Book. Edited by Kenelm Edgcumbe. Pp. viii + 456. (London: Whittaker and Co., 1903.) Price 3*s.* 6*d.*

This little book differs in several respects from the ordinary type of pocket book; it possesses the usual features—a limp cover, round corners, gilt edges, and a weight quite unsuited to the pocket—which serve to characterise the "pocket book," but in the arrangement of the matter it rather resembles a small encyclopædia. Each branch of electrical engineering is dealt with in a separate section or chapter, which may be read consecutively as if it were a brief treatise on the subject. The method has much to recommend it; the electrical engineer who comes across some problem in a branch with which he is not familiar can turn up the section dealing with that branch and read a summary of the whole subject; numerous references to recent papers will greatly help him in finding the particulars which he wants. There are, of course, also a number of tables of the constants more generally required. The treatment is not very even; thus whilst generating machinery—dynamos, alternators, and motors—receives full consideration in 100 pages or more, only four pages are given to electric lamps and lighting, and the information given therein is quite inadequate. The diagrams and illustrations are clearer than those usually to be found in books of this class.

M. S.

Astronomischer Jahresbericht. By Walter F. Wislicenus. Band iv. Pp. xxxii + 648. (Berlin: Georg Reimer, 1903.)

This, the fourth issue of this most valuable and useful volume, contains the references and a brief summary of contents of the astronomical literature published last year. The work is of the same high standard as in former years, and casts great credit on the labours of Herr Wislicenus and his joint compilers. This year-book is so well known to astronomers, and has been found so valuable by them, that it is hardly necessary to dwell either on the general arrangement of the subject or on the method of treatment. The main object of the compilers was to make as perfect a record as possible of all the published papers on this subject, yet to keep the book from becoming too bulky. This they have succeeded in doing, in spite of the fact that many of the abstracts of lengthy papers are very complete.

Now that the Royal Society has published the first annual issue of this branch of science (E. Astronomy) in the "International Catalogue of Scientific Literature," it seems possible that there will scarcely be room for both of these compilations, since the more perfect they become the more closely will they resemble each other. This question, however, the future will no doubt settle. There is, nevertheless, one main difference between them, in that the volume before us summarises the contents of each paper to which reference is made, while that of the "International Catalogue" is restricted to the bare references.

W. J. S. L.

Practical Management of Pure Yeast. By Alfred Jörgensen. Translated by R. Grey. Pp. viii + 60. (London: the *Brewing Trade Review*, 1903.)

This useful little work might have received with advantage a title better descriptive of its contents. It contains a condensed account of the biological methods which are employed in the author's well-known laboratory in the pure culture and analysis of alcohol-producing yeasts. According to the preface, the leading purpose of this treatise is to enlighten the so-called practical man in the methods of investigation employed by the zymotechnologist, so that in the future the practical man and the technologist may work together with better understanding at the many important and difficult problems which are encountered in the processes of the fermentation industries. No doubt the little book is well calculated to fulfil its object if only the practical man will read it, and we hope it will be in much demand for this purpose. But whatever may be the success of the book in this direction, it undoubtedly deserves the careful attention of all zymotechnologists, as it indicates the lines on which a well-known investigator of great experience is working with a view to the solution of many interesting and complicated problems in connection with the organisms of fermentation. The last words on the biological methods of analysis and the technical employment of pure cultures of yeast are still a very long way from being spoken, but as an advance towards this end we cordially recommend the work to the attention of all interested in the biological aspect of the fermentation industries.

A. J. B.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Variation of Atmospheric Absorption.

I SHOULD be pleased to know how far some observations on the change in the average absorption of the terrestrial atmosphere in this country during the last two years have been confirmed by observations elsewhere. The following table gives the mean of the best of these, made at Washington in the autumn of 1901, the spring and autumn of 1902, and in the winter, spring, and summer of 1903.

Coefficients of Transmission for Zenith Sun.

	μ	μ	μ	μ	μ	μ	μ	μ
Wave-length... ...	0·50	0·60	0·70	0·80	0·90	1·00	1·20	1·60
Mean of observations, 1901–1902.	0·765	0·769	0·857	0·897	0·910	0·921	0·933	0·930
Mean of observations during 1903	0·627	0·692	0·753	0·797	0·825	0·847	0·874	0·909
Excess of transmissibility of 1901–1902 over that of 1903	20%	10%	13%	12%	10%	8·4%	6·5%	2·3%

The decrease in the transmissibility of the air this year as compared with the last is so marked that some local effect on climate and vegetable growth might seem to be probable. Whether the unusual coolness of the summer, reported both in America and abroad, is connected with it may be a subject for speculation. S. P. LANGLEY.

Smithsonian Institution, Washington, October 22.

Heating Effect of the Radium Emanation.

THE very important and fundamental experiments described by Profs. E. Rutherford and H. T. Barnes in NATURE of October 29 will have been read with the greatest interest. Owing to the importance of the subject, I should like to direct the authors' attention to some points in their comment and explanation which do not appear to me to be quite clear, and if I can draw from them some more detailed discussion this letter will have served its purpose.

The general conclusion arrived at by the authors is that "more than two-thirds of the heating effect is not due to the radium at all, but to the radio-active emanation which it produces from itself." If I understand the description of their experiments correctly, these seem to me, however, to point to the fact that it is the "excited activity" and not the emanation that is the cause of the heating. Apparently de-emanated radium gives out an amount of heat at a rate which falls in a few hours to a minimum and then slowly recovers. Now the emanation itself begins to form again at once, so that on the authors' hypothesis the heating effect should start with a minimum and then gradually increase. The activity of the radium measured by electric methods follows the course of the heating effect, and, as Messrs. Rutherford and Soddy have explained (*Phil. Mag.*, April, *not* May as quoted by the authors), this is due to the fact that the de-emanated radium has still the excited activity attached to it, and this activity decays in the course of a few hours. When the excited activity is gone there is nothing but radium left, and the further changes are due to the re-formation of the emanation and its subsequent change into excited activity. During the course of the first few hours there is, therefore, very little emanation, but there is excited activity which falls to a minimum and then slowly grows again. Does not the explanation which holds for the activity also hold for the heating effect, and would it not follow that the parallelism of heating effect lies with the amount of the excited activity present, and should be assigned to it rather than to the emanation?

Similarly, the emanation, according to the authors, does not give its full heating power at first, but the heating effect rises to a maximum in the course of the first few hours. If the emanation is the cause of the heat, why this slow rise? Here again the effect seems proportional to the amount of excited activity present, and not to the amount of the emanation. The connection of heating power with the emission of α rays also requires further elucidation, and the information given by the authors is not, I believe, sufficient to prove their case. It is only with great diffidence that I address these remarks to you, because Prof. Rutherford knows the whole subject at first hand, and his judgment is more likely to be correct than mine. Nevertheless, one likes to know whether others have felt the same difficulty, and whether the apparent disagreement is one of misunderstanding or has some more deep-seated cause. ARTHUR SCHUSTER.

The Owens College, Manchester, November 2.

Radium and Plants.

THE sensibility of protoplasm towards the radiations of radium is a matter of so much importance that a few preliminary experiments I have carried out on plants may be of interest.

The first experiment I made in this direction was with cress seedlings. About 100 seeds were uniformly distributed over the surface of some moist sand contained in a flower saucer, and a tube containing 5 mgrs. of pure radium bromide supported at a height of 1 cm. over the centre of the sand surface. During the experiment the saucer, covered with a glass shade, was kept in the dark. It was hoped that this arrangement would show whether the radiations are harmful or not to the sensitive cells of seedlings, and at the same time indicate if they are able to act as a stimulus to evoke positive or negative curvatures.

After the germination of the seeds, which took place within two days nearly simultaneously all over the sand, the growth of all the seedlings was nearly uniform. But close comparison showed that the seedlings immediately under the radium tube were to some small extent retarded in their development. The retardation was apparent in the seedlings situated within a radius of about 2 cm. from the radium bromide. Besides being smaller, these seedlings developed somewhat fewer and shorter root-hairs than those nearer the margin of the sand.

In the subsequent growth the presence of the radium evoked no curvatures in the little plants close by it, or in those more removed. Nor did it appear to exercise any noxious effects, other than the retardation just described, on the seedlings within the period of the experiment, viz. thirteen days. The plants grew up beside it and against the glass containing it, neither influenced by it nor hurt by it, so far as one could see.

This experiment was repeated on two other occasions (one experiment lasting three days after germination and the other lasting four days) with the same result, viz. no curvature was evoked, but the seedlings close under the radium bromide were slightly retarded in their growth.

In order to determine if motile organisms are sensitive to the radiations I enclosed the radium tube in a vessel of water containing large quantities of *Volvox globator.* Extraneous light was cut off from the experiment. After twenty hours many of the Volvox colonies had sunk to the bottom of the vessel, but they were evenly distributed over the bottom, and were neither aggregated under the tube nor dispersed away from it. Those that were still swimming in the water were also uniformly distributed through it, some actually in contact with the radium tube and some far away from it, but showing no sign of being attracted towards it, or of being repelled from it.

It is apparent from these few experiments that the radiations emitted by radium bromide are not able to produce marked effects in a short time on these vegetable cells and tissues. Even the phosphorescent light (which is quite perceptible to the eye under suitable conditions) emitted by the radium bromide is too feeble to be effective in calling out a phototactic response. HENRY H. DIXON.

Botanical Laboratory, Trinity College, Dublin.

Solar and Magnetic Disturbances.

THE Kew photographic curves showed appreciable magnetic disturbances of a normal type on the evening of October 30 and early morning of October 31, but the first distinct precursor of the magnetic storm was an exceptionally sudden movement at about 6h. 3m. a.m. on October 31, shown alike in the declination, horizontal force and vertical force curves. This movement was largest in the horizontal force, where there was a sudden increase of about 60 γ ($1\ \gamma \equiv 1 \times 10^{-5}$ C.G.S. unit). In the declination there was a simultaneous movement of about 7′ to the west, apparently preceded by a very tiny movement to the east, lasting too short a time to be distinctly shown. The first large movements commenced about 6.45 a.m., when there was a movement of the declination needle to the west through about 34′, and a diminution of 240 γ in the horizontal force. The storm was most violent between 10 a.m. and 7 p.m. on October 31, but there was a large amount of disturbance until 3 or 4 a.m. on November 1.

The traces from the Kew magnetographs—declination, horizontal force and vertical force alike—went off the sheet repeatedly, so that the full extent of the disturbance cannot be derived from them. A declination magnetograph, however, of lesser sensitiveness recorded apparently the complete movement, and showed a range of about 2° 12′. Between 1 and 7 p.m. there were at least twenty to and fro oscillations of the declination needle—each occurring in but a few minutes of time—the amplitude of which exceeded 20′. In addition to these there was a very large number of smaller oscillations. At times these followed one another so rapidly that they can hardly be seen apart on the photographic sheet. In the horizontal force there were also very numerous oscillations. The general tendency from 7 a.m. to 10.30 a.m. was towards a reduction of the force. From 10.30 a.m. to 1 p.m. the oscillations were about a value not far from the normal. At about 1 p.m. there commenced a rapid rise, which in twenty minutes amounted to about 690 γ, the curve going off the sheet. During the next two and a half hours the trace was often off the sheet. Between 3.50 and 5.10 p.m. the trace crossed the sheet from edge to edge, representing a change of about 750 γ, or somewhat more than one twenty-fifth of the value of the whole horizontal force. The vertical force disturbance was small at first, and did not become really large until nearly noon on October 31. From noon to 7 p.m. there were numerous large oscillations, the curve going off the sheet repeatedly on one side. At about 1.40 p.m. there was an oscillation where, in the course of five or six minutes, there was a decrease and increase of more than 350 γ. The trace remained off the sheet from about 3.30 to 5 p.m. Between 5.10 and 5.50 p.m. the force diminished about 450 γ.

The storm is much the most notable recorded at Kew since February 13–14, 1892. CHARLES CHREE.

National Physical Laboratory, Richmond, Surrey, November 3.

IN connection with the magnetic storm of Saturday last, October 31, it may be of interest to record that observations made between 10 and 11 a.m. on that day by Prof. Callendar and myself showed a violent distortion and reversal of the C line of hydrogen in the neighbourhood of the great sunspot group, which was then a little past the central meridian. A notable feature was the apparent detachment of a portion of the dark C line, the separated part presenting the appearance of a cloudy patch, displaced towards the violet by about three tenth-metres. The observations were unfortunately interrupted by clouds.

A reversal of the C line over the same spot had been observed on the two preceding days, but though on these occasions the bright line was more brilliant than on October 31 there was much less distortion of the dark line.

A. FOWLER.

Royal College of Science, South Kensington, November 3.

Dr. Shaw's Address at the British Association.

I HAVE received the following letter from Sir Arthur Mitchell, K.C.B., who has been for long closely identified with the Scottish Meteorological Society, both as a scientific worker and as an administrator, and who was one of the founders of the Ben Nevis Observatory, and I send it to you as it expresses what I am sure must have been the feeling of meteorologists on reading Dr. Shaw's otherwise admirable and inspiring address on methods of meteorological investigation.

34 Drummond Place,
Edinburgh,
October 15.

Dear Mr. Omond,—

Dr. Shaw's address to the subsection of astronomy and meteorology of the British Association in September last, by its appearance in NATURE of September 17 has quickly and effectively reached the whole scientific world, and it is misleading in important directions, quite unintentionally, I believe.

The absence of all reference to the meteorological work done by Buchan, Stevenson, Aitken, Buchanan, Murray, yourself and others will probably receive an interpretation which I hope is erroneous, for I cannot think that Dr. Shaw would designedly belittle the valuable work these men have done, which is recognised as being of a high character all over the world.

But it seems to me more remarkable that Dr. Shaw should have made no special reference to the work of the Ben Nevis Observatories. In that work a very great, costly and laborious effort has been made to advance meteorology and to add to knowledge, and this has been done mainly through private enterprise, under the guidance of the foremost scientific men of our time, including Kelvin, Tait, Buchan, Murray, Copeland, Aitken, Buchanan, Stevenson, and many others. The discussion of the outcome of this great experiment in connection with the physics of the atmosphere has only recently begun. It cannot be quickly finished, much time by many experts must be given to it, and it cannot fail to cost a large amount of money.

My special object in writing to you is to suggest that, as honorary secretary of the Ben Nevis directors, you should in some way supply what I regard as an incompleteness in Dr. Shaw's address by briefly stating how the work of the Ben Nevis Observatories now stands, and what prospects there are of its yielding further important additions to knowledge.

Very faithfully yours,
ARTHUR MITCHELL.

In accordance with Sir Arthur's suggestion I beg to make the following statement explanatory of the present position of the Ben Nevis Observatories, and to note briefly the work carried on at and in connection with these observatories.

When the observatory on Ben Nevis was opened twenty years ago very little was known about the condition of the atmosphere above a few hundred feet height over the British Islands. The first object aimed at was to determine the meteorological constants for that position, and the relations of the air there to that at sea-level in the neighbourhood. This latter part of the work has only been adequately carried out since the establishment of the Fort William Observatory in 1890. The observations down to the end of 1892 have been published in two volumes of the *Transactions* of the Royal Society of Edinburgh (Nos. 34 and 42). The first of these was printed at the expense of the Royal Society of Edinburgh, and the second at the joint cost of the Royal Societies of London and Edinburgh. Another volume is in the press, and will be issued shortly.

The constants referred to are:—(1) The average value at each hour of the day for each month of the year of barometric pressure, temperature of the air, humidity, rainfall, direction and force of wind, amount of cloud and sunshine on Ben Nevis. (2) The relation of each of these to the corresponding sea-level values at Fort William. Immediately arising from these average values is the question of the changes induced on them, especially on the second series, by different conditions of weather—that is, the determination of the vertical gradients of pressure, temperature, &c., under varying atmospheric conditions. This discussion has been partly carried out, and the more important results arrived at are summarised in papers appended to the two volumes of observations.

One of the most interesting practical aspects of the Ben Nevis records is their application to the reduction of barometric readings to sea-level, a subject which is at present engaging great attention in this country, in the United

States, and, indeed, wherever meteorology is studied. The other subjects treated in these papers include:—

(1) The changes in the hourly variation of the barometer in fine and in cloudy weather at Ben Nevis, Fort William, and several other stations.

(2) The general meteorological conditions on Ben Nevis in clear and in foggy weather.

(3) Atmospheric dust on Ben Nevis.

(4) The pumping effect on a barometer of strong winds.

(5) The difference in the direction of the wind at Ben Nevis from that at sea-level.

(6) The change of temperature with height in anti-cyclones.

(7) The diurnal ranges of the Ben Nevis and Fort William barometers when both are reduced to sea-level by the usual tables.

(8) The diurnal range of the variability of temperature from day to day at Ben Nevis and some other places.

(9) The meteorological conditions at Ben Nevis during the severe frost of January and February, 1895.

(10) The relation of wind direction to temperature and to rainfall at Ben Nevis.

The establishment of the Ben Nevis Observatories has provided meteorological data of a character unique in this country, and, indeed, in the world, owing to the position of Ben Nevis as a high-level station placed right in one of the storm-tracks of the Atlantic. But it has also led to investigations which could not otherwise have been carried out, for no increase in the amount or quality of low-level observations would have supplied the necessary data, and the high-level records got from kites or balloons are too fragmentary for the purpose.

The observatories were built with money subscribed by the public, and up to this time have been supported by subscriptions, aided by an annual payment of 100*l.* for the Ben Nevis Observatory and 250*l.* for the Fort William Observatory from the Parliamentary grant of 15,300*l.* given annually for meteorological purposes. What their future position may be depends on the recommendations of the Parliamentary Committee of Inquiry into the administration of this grant now sitting, but whether Parliament gives the money necessary to carry them on, or whether they are closed and abandoned, as they assuredly will be if not taken over by the State, the work done at and in connection with these observatories is a record of investigation which will be growingly studied by meteorologists.

Edinburgh, October 17. R. T. OMOND.

No one is more conscious of the shortcomings and omissions of the address than its author. One correction I should like to make here. The joint editors of the *Meteorologische Zeitschrift* are Dr. Hann and Dr. Hellmann; Dr. Pernter is associated with the journal as "Herausgeber."

I cannot fail to be aware that, with perfect propriety, I might have devoted a large part, or even the whole, of the address to the obligations of meteorology to private enterprise in this country. In that case it would have been a different, perhaps a better, address, but I will ask your readers to believe that any omissions of that kind which they detect and regret were not due to a desire to belittle anything except the address itself.

In one sentence I did explicitly refer to Edinburgh and Ben Nevis. I cannot altogether emulate the achievement of Mr. Puff, who managed to extract so much meaning from a shake of Lord Burleigh's head, but I should like to say that if Sir Arthur Mitchell had used an appropriate magnifying power, and had got it properly focused upon that sentence, he would have read the following opinion which the mention of Ben Nevis always suggests to my mind, "that if means were found for endowing a chair of meteorology in the University of Edinburgh, and one of the distinguished Scottish meteorologists, whose names require no announcement from the chair to make them known to the British Association and far beyond, were appointed thereto, a most important and productive step would be taken towards the solution of the many problems connected with the great Scottish work of the Ben Nevis Observatories, the twenty-first annual report of which Dr. Buchan will present to the Association." W. N. SHAW.

October 21.

Weather Changes and the Appearance of Scum on Ponds.

IF any of your readers could explain an interesting natural phenomenon constantly occurring here we should be very grateful. It is simply that, invariably before any decided change of weather, there comes up a scum on the surface of the pool or small lake which skirts our south and east lawns—part of the pleasure grounds surrounding the mansion. Sometimes it looks like soapy water, but at other times it is black, and makes the breasts of our swans as black as ink just above the water-line. Then the scum will suddenly disappear, and the swans' breasts become white again. Our geological formation is the junction of the Upper Greensand and the Lower Chalk. The bottom of our lake is chalk; it is fed by springs, and the stream formed by its overflow runs finally into the Thames. It is shallow, and is surrounded by large trees. There are at present eight swans on it, also many moorhens and wild duck, and quantities of fish, which attract herons; kingfishers live in the bank, which is very high on the far side. There is also an island with large trees and a dense undergrowth. PLATANUS ORIENTALIS.

Aston Rowant, Oxon.

WITH reference to the letter of "Platanus orientalis," it seems to me that a possible explanation of the appearance of dirty scum on the surface of the pond before any decided change of weather may be that a sudden change of barometric pressure may accelerate the flow of springs rising through the chalk of the floor of the pond. This would carry up to the surface of the water some of the fine mud which had rested on the chalk, or even lodged in crevices within it. When the flow of the springs diminished or ceased, the sediment would naturally subside once more. It would be interesting to keep an exact record of the appearance of the scum and of the variations of atmospheric temperature, pressure, and the rainfall by automatic recording instruments.

Without knowing the local conditions it would be impossible to speak definitely as to the sufficiency of this explanation.

Another that occurs to me is that, if the sediment at the bottom of the pond is of a flocculent character, its movements may be due to the same cause as those of the precipitate in a "storm-glass," whatever that cause may be; but in that case the appearance would probably be limited to dead calm weather.

It is possible that the scum may be organic, and it would be desirable to have it examined microscopically by a student of limno-plankton.

HUGH ROBERT MILL.

Cranial Casts.

IN the number of NATURE which arrived here to-day there is a report of the interesting presidential address delivered by Prof. Symington in Section H at the British Association's recent meeting. In this report there are several statements which are likely to prove misleading to those who are not familiar with the literature relating to brain-casts. The reader might imagine (see p. 540) that this was an entirely new branch of research suggested by Dr. Forsyth Major's work on the subfossil Lemuroids (1898) and only fully exploited by Prof. Schwalbe in 1902. This, of course, cannot be the meaning which Prof. Symington intended to convey, because he is quite familiar with the scores of cranial casts made in such profusion by Prof. Gervais in the years 1867–1871, and by a long line of anatomists and palæontologists both before and since that time, and with the valuable contributions to knowledge which have resulted from this fertile branch of study; in fact, Prof. Symington happened to visit the work-room in the Royal College of Surgeons in 1901 when I was examining and describing the considerable collection of such casts (representing more than one hundred genera) which have been brought together by the late Sir William Flower and the present conservator, Prof. C. Stewart. (And, with reference to Prof. Symington's remarks on curators, I may mention that no one more fully recognises the value of cranial casts than the present conservator of the Royal College of Surgeons' Museum.)

But more remarkable than this is the statement :—"This method has been applied with marked success to the determination of the characters of the brain in various fossil lemurs by Dr. Forsyth Major and Prof. R. Burckhardt" (p. 540). The "*marked success*" of Prof. Burckhardt consisted in flatly contradicting in almost every essential feature the *correct* account of the same specimen given by Dr. F. Major, as I have pointed out in a work (*Trans.* Linnean Soc., February, see especially p. 365) published seven months ago. Prof. Symington could not have chosen out of the scores of memoirs on cranial casts an example more likely to bring contempt on the method he so eloquently and so justly extols.

His statement that "so far as prehistoric man is concerned, we can never hope to have any direct evidence of the condition" of the brain is stultified by the fact (which I mentioned fifteen months ago in the *Journ. of Anat. and Phys.*, July, 1902) that I have in my possession a large series of actual prehistoric brains with the crania from which they were derived. Many of these are so excellently preserved that every detail of the convolutionary pattern can be recognised, and by transferring it to the surface of the cranial cast an accurate model showing exactly the size, shape, and arrangement of the sulci with perfect accuracy can be obtained. That I am not exaggerating the excellence of these prehistoric relics may be seen from the brain fragment (D. 691) in the galleries of the Royal College of Surgeons' Museum, especially when I add that I possess whole hemispheres in even a better state of preservation.

As to the method of interpreting human brain casts, if we follow Prof. Symington's advice and begin by identifying the Sylvian fissure as the groove produced by the orbito-sphenoid ("as is well known, the marked prominence at the base of the human skull separating the anterior from the middle fossa fits into the deep cleft between the frontal and temporal lobes of the brain") we shall fall into grave error in many cases. It sometimes happens (in more than 50 per cent. of my collection of "Greek" and "Turkish" hemispheres) that the orbito-sphenoid lies far in front of (and not *in*) the Sylvian fissure, mapping out a great "post-orbital limbus" (Spitzka) of the frontal lobe, which has slipped over into the middle cranial fossa. I have seen the Sylvian fissure lying as far as 1 cm. behind the orbito-sphenoid (in a Syrian brain), and a prominent crest derived from the alisphenoid projecting into it.

It is surprising to find Prof. Symington repeating that time-worn fallacy :—the inferior frontal convolution "is well known to be much more highly developed in man than in the anthropoid apes" (p. 541). For if we follow the lead of Profs. Marchand and Cunningham—and to anyone who really examines the facts of the case there is no other alternative—the inferior frontal sulcus is represented in the apes by the sulcus rectus, and the inferior frontal convolution is *relatively much bigger* in the apes than in man.

Every anthropologist will cordially re-echo Prof. Symington's wish that information concerning large series of non-European brains may soon be forthcoming. But that we know so little concerning these other types of the human brain is not wholly the fault of the people who have access to such material. The chief blame must rest on those anatomists who, with every advantage which museums, libraries, and trained assistants confer, have done so little to provide data relating to the European types of brain which are of any anthropological value. I know several anatomists in various parts of the world who have the material and are merely awaiting a "lead" as to which features of the brain are of anthropological importance and are worthy of being recorded.

I have recently met with the same difficulty. After having examined six hundred Egyptian, Soudanese, and a varied assortment of other non-European brains, I am unable to acquire from the writings of European anatomists just that information of the European types of brain which I need for purposes of comparison; moreover, I am unable to publish the anthropological results of my work in any satisfactory form until I have discussed such purely morphological questions as the real constitution of the fissure of Sylvius and have unravelled the intricacies of the parieto-occipital regions of the brain. When the "home" anatomists have done their part of the work, the rest will soon follow.

G. ELLIOT SMITH.

The School of Medicine, Cairo, October 7.

I HAVE to thank you for your courtesy in allowing me the opportunity of reading a letter which Prof. G. Elliot Smith has addressed to you, criticising various statements in my presidential address in Section H of the British Association at Southport. Prof. Smith has raised so many points that I have only time, at present, to reply to a few of them.

What a reader "might imagine" I will not attempt to picture, but I certainly had no intention of implying that only the three investigators I happened to mention had worked at the subject of cranial casts, or that "it was an entirely new branch of research."

I endeavoured to show that the examination of a skull was necessarily incomplete until the interior of its cranial cavity was exposed and cast, and that, although such methods were calculated to afford valuable information as to the relation between the external and internal surfaces of the cranial wall, and to give an important indication of the form of the brain it once contained, yet the curators of museums appeared to have an invincible objection to making the necessary section, and the practice of taking casts of the cranial cavity had been too much neglected by craniologists. I gave as an illustration of the usual custom of preserving skulls entire the Hunterian Museum in London, and this selection appears to have been a source of offence to Prof. Smith, although he does not disprove my statement. His remarks as to the number of casts of different genera in that museum are quite beside the mark. I was referring to the very large collection of human skulls, and, so far as I have been able to ascertain, no systematic attempt has been made to examine more than a small fraction of them in this way. I know that many curators object strongly to the skulls under their care being bisected, and believe that at any rate their appearance would be seriously affected by such an operation. I ventured to advocate a method which, in my opinion, has not been followed to any marked extent in the collection of human crania in the Hunterian Museum or elsewhere in this country, and trust I was at liberty to do this without it being regarded as a personal attack upon the conservator, for whom I have the very highest regard.

Prof. Smith objects to my statement that "we can never hope to have any direct evidence of the condition of the higher nerve centres of prehistoric man" on the ground that he has collected a large series of such brains from Egyptian cemeteries, and he refers to a paper he published in the *Journal of Anatomy and Physiology* last year. I had the pleasure of reading his paper when it appeared, and although his specimens were of great interest, it seemed to me that their state of preservation was not sufficiently good to be of much use for the accurate determination of the numerous details which it would be necessary to know, when comparing them with modern brains. The specimens had undergone marked diminution in size, and in places were considerably distorted. Further, from the actual photographs (Plate xiv.) which he gave it appeared to me that a considerable restoration would be needed when attempting to limit the boundaries of the cerebral fissures. I hope that the impression left upon my mind from the perusal of his paper may be an erroneous one, and that the additional evidence promised by Prof. Smith will dissipate my doubts.

I do not quite appreciate the cautiousness of those anatomists who are waiting for a "lead" before describing the specimens of non-European brains in their possession. The numerous memoirs that have been hitherto published on the cerebral convolutions are based almost entirely upon the study of European brains, and what we obviously require is a careful and an unbiased account of the cerebral fissures and convolutions of other races. If Prof. Smith and his friends wait until the favoured "home" anatomists agree as to the "types" of European brains, and until he has definitely settled for us all the morphological problems connected with the cerebral cortex, we shall, I fear, need a large store of patience.

In conclusion, I should like to assure Prof. Smith that if I did not refer specially to his work it was not because I do not appreciate its value, but on account of the limitations in time and space necessary in the circumstances of my address.

J. SYMINGTON.

October 19.

MAGNETIC STORMS, AURORÆ AND SOLAR PHENOMENA.

The attention of the whole civilised world has this year been directed to the importance of finding a connection between terrestrial and solar variations, but the phenomena recorded last Saturday in the nature of a great magnetic storm and a brilliant aurora borealis have perhaps brought home to many the desirability of pursuing such investigations which may help us to be forewarned, and therefore forearmed.

The enormous development of the telegraph, telephone, cable, and other applications of electricity since the date of the last great magnetic storm has caused the disturbance to be more generally observed than was previously perhaps the case.

Practically the world's whole telegraph system was upset, and information from this country, France, the United States and other lands shows that for several hours communication was almost completely interrupted.

According to the *Daily Mail* the London telegraphic department characterised the storm as the most extraordinary ever experienced. Messages dispatched on Saturday from Russia, Spain, Switzerland, France, Germany, Belgium, and other countries, which would ordinarily have been received an hour or less after transmission, were still slowly coming through on Sunday morning. Mr. Gavey, the electrician-in-chief to the Post Office, in an interview with a *St. James's Gazette* representative, said the storm was the most severe that had been experienced for the last twelve years. The effects of it were first felt at St. Martin's-le-Grand at 6.45 a.m. on Saturday, and they continued until five in the afternoon. It was eight o'clock before the storm had completely disappeared.

The New York correspondent of the *Daily Telegraph* states that the magnetic disturbance was felt practically everywhere in the United States, affecting the great cable companies for a time, while the telegraph wires in all directions from Chicago felt the effect; the long distance telephones were similarly troubled. The disturbance lasted eight hours, and at its climax "there were 675 volts of electricity—enough to kill a man—in the wires, without any batteries being connected to them." During the magnetic storm which occurred in 1871 the Eastern Telegraph Company showed that there was an earth current of 170 volts on their Suez-Aden line.

The *Times* correspondent in Paris states that according to a Press communication from the French Under-Secretary of State for Posts and Telegraphs the magnetic phenomenon extended in all directions, but with somewhat less intensity towards the north-west; the telegraph office was from nine o'clock in the morning deprived of communication with the greater part of the French towns and the adjoining districts. It was subsequently also cut off from communication with America, Spain, Portugal, Italy, Algeria, Tunis, and places beyond those countries. At 4.40 p.m. communication was re-established; it was again interrupted at 5.30 p.m., but a little after sunset almost all communications were found to be restored.

It is interesting to note that the effect of a magnetic storm on a telegraphic system may be modified in two, if not more, ways, and this was done in the case of our own Post Office. One method, as stated by Mr. Gavey, is to join two wires, thus forming a loop, and in this way eliminate the earth from the circuit. The other means is to employ condensers; these, when connected up with the circuit, stop a continuous current such as is set up by magnetic disturbances.

In several regions the magnetic disturbance was accompanied by a display of the aurora. In New York on Saturday morning the northern sky was described as "a dazzling display of light and colour"; it was first seen in the city at two o'clock, but faded away at four. In Ireland and Scotland during Saturday evening the aurora was also observed.

A message from the Sydney correspondent of the *Times* states that a beautiful Aurora Australis was seen there on Saturday night, the streamers reaching nearly to the zenith.

Earthquakes also seem to have been recorded as well. On Friday and Saturday two undulating shocks were felt at Benevento and Avellino, in Italy, the first lasting two seconds, and the other a minute.

In Essex several distinct earthquake shocks were felt at Saffron Walden. At midnight on Saturday one shock is stated to have lasted five minutes. These were repeated at 5.50 and 9.30 on Sunday morning. At Debenham, four miles distant, shocks were felt on Monday sufficiently strong to cause small articles to fall to the ground.

Tuesday's *Daily Mail* publishes a telegram from Simla (dated November 2) in which it is stated that terrible earthquakes occurred at Turshiz, near Turbati-haideri, in Persia. Unfortunately, the time of occurrence was not mentioned, and up to the moment of writing (Tuesday evening) the news has not been corroborated.

In a communication to the writer from Stonyhurst Father Cortie writes:—"We had a magnificent magnetic storm on Saturday and Sunday, the biggest ever recorded here. The declination magnet swung through 2° 46′. The spot of light for the horizontal force travelled several times right off the pages on the drum."

From the above brief summary of the information to hand it will be gathered that we have experienced a storm of quite considerable magnitude, not perhaps the worst that has ever been recorded, but at any rate a "great" disturbance.

Two important questions now arise. What is the cause of these sudden magnetic phenomena? Can they be predicted?

The first of these questions is one which is answered differently by different investigators. Some think that there exists a common cause external to the sun, while others are agreed that the storms originate from the sun itself; there are also many who go more into detail and are inclined to favour the view that they are caused by sunspots.

In the last mentioned case then it is natural to conclude that when there is a large spot we should experience a magnetic storm, and when there are no spots storms should be absent. This, however, is not the case. The true explanation must account for the three possibilities of the appearance of these storms.

(1) A large spot *with accompanying* magnetic disturbance and auroræ.

(2) A larger spot *with no accompanying* magnetic disturbance and auroræ.

(3) No great apparent solar activity, but magnetic disturbance and auroræ.

Since sunspots cannot be held to satisfy these necessary conditions, are there other solar disturbances which can be utilised? Yes, there are the prominences which were first seen projecting beyond the dark limb of the moon during total solar eclipses. Up to the year 1868 these were the only opportunities when such solar appendages could be observed, but during that year a method was discovered by Sir Norman Lockyer and Dr. Janssen by which they could be seen on the sun's limb at any time without the necessity of waiting for these brief opportunities. It was not, however, until the year 1870 that regular observations of the limb of the sun showing these indications of solar activity were

commenced, but, thanks to the magnificent work of Respighi, Tacchini, Ricco, and Mascari, we have practically a continuous record of them up to the present time.

The question then arises, are these prominences in any way related to the occurrence of magnetic storms? Before answering this, a few preliminary remarks may be made.

In the first place the number of spots on the sun is nearly always insignificant compared to the number of prominences. Prominences are, therefore, of greater relative importance than spots.

While sunspots are restricted to practically a narrow zone ($\pm 5^\circ$ to $\pm 35^\circ$) on each side of the solar equator, prominences can and do occur all over the sun's disc. Again, the general trend of the spot circulation is from the higher to the lower latitude, while in the case of prominence the reverse happens. In some years we have a great number of prominences near the solar equator, while in other years they are observed also in great numbers near the solar poles. A glance at some curves recently published in this Journal (vol. lxviii. p. 257, July 16) will shown not only the general drift

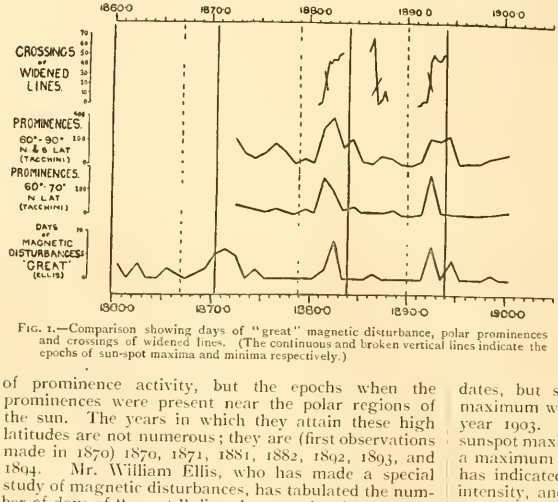

FIG. 1.—Comparison showing days of "great" magnetic disturbance, polar prominences and crossings of widened lines. (The continuous and broken vertical lines indicate the epochs of sun-spot maxima and minima respectively.)

of prominence activity, but the epochs when the prominences were present near the polar regions of the sun. The years in which they attain these high latitudes are not numerous; they are (first observations made in 1870) 1870, 1871, 1881, 1882, 1892, 1893, and 1894. Mr. William Ellis, who has made a special study of magnetic disturbances, has tabulated the number of days of "great" disturbances, that is, those recorded at Greenwich above a certain standard. These are utilised to form the following table:—

Date	Number of years	Number of days of "great" magnetic disturbances	Average per year
1870–1872	3	16	5·33
1873–1880	8	2	0·25
1881–1882	3	10	3·33
1883–1891	9	1	0·11
1892–1894	3	7	2·33
1895–1900	6	2	0·33

Another and perhaps more striking way of showing the coincidence of the epochs of the occurrence of days of magnetic disturbances and polar prominences is illustrated in the accompanying figure (*see* NATURE, February 19, vol. lxvii.).

The continuous and broken vertical lines indicate the epochs of maxima and minima sunspots, showing that the former tend to occur later than the peaks of the magnetic curves. In this diagram Respighi's observations of polar prominences made during the years 1870 and 1871 are not included, but their mean latitudes for each hemisphere during these years were $\pm 70^\circ$.

It will thus be seen from the above that the occurrence of polar prominences is closely associated, at any rate in time, with great magnetic storms, and, therefore, with auroræ, which nearly always accompany them. Further, prominences fulfil the three conditions mentioned previously in this article, for they can occur when there are spots and also when there are none.

One argument used against the prominence theory is that the polar prominences are "quiet" prominences and therefore are not likely or are possibly not capable of producing such large terrestrial effects. The critic may, however, have forgotten to consider the possible and natural conclusion that the appearance of prominences in high latitudes may at least be simply an indication of greater action occurring nearer the equatorial regions with consequent greater extension of the disturbed region towards the polar zones.

That the polar regions of the sun are sometimes greatly disturbed is again emphasised by the presence of enormous streamers that are seen in those regions during some total solar eclipses. Further, these polar streamers are observed only at those times when the prominences approach high latitudes. Here again we have good cause to doubt the inability of these polar prominences as disturbing agents. Even if the prominences be not conceded to be the initial cause of magnetic storms, their gradual changes of position towards the solar poles may afford a valuable means of forecasting the epochs of magnetic disturbances.

From the facts before us let us consider the question of forecasting the years in which magnetic storms should occur. If the reader will glance at the figure accompanying this article and continue the curves on the assumption that the last sunspot minimum occurred in 1901·5 and the next maximum in 1905, he will most probably make a maximum fall between these two dates, but somewhat nearer the latter; in fact the maximum would have been placed in the middle of the year 1903. It will be noticed, however, that at the sunspot maximum of 1870 the disturbance curve reaches a maximum a year after 1870. A recent investigation has indicated that all sunspot cycles are not alike in intensity, and that the cycle commencing in 1901 may probably correspond to that which commenced in 1867. If, therefore, the coming sunspot maximum should attain the same dimensions as that reached in 1870, it seems quite possible that the magnetic disturbance curve for the present cycle should correspond to that portion commencing about 1867. If this be so, then not only should polar prominences be recorded from the years 1903 to 1906 or 1907, but during these years "great" magnetic disturbance will be liable to occur. As shown in the previous table, no less than 16 of Ellis's "great" magnetic storms occurred between 1870 and 1872; also two occurred in 1869 and one in 1868, so that if we consider the present year to correspond to 1868 there is much in store for us. It may be mentioned also that since the years 1899 and 1900 the prominences have exhibited the tendency to attain high latitudes, so that there seems every reason to suppose that magnetic storms and auroræ may be experienced during the course of the next three or four years, after which there will be a cessation for about ten or eleven years. WILLIAM J. S. LOCKYER.

A NEW NATURAL HISTORY.[1]

IN our notice of the earlier portion we stated that it was then impossible to arrive at a definite conclusion as to the merits of this work, since the section in question was more or less introductory in its nature. Now that the author has got into the full swing of his subject, such a judgment is possible, and we have much pleasure in saying that our own verdict is in the main one of decided approbation. The author has had practically a new field before him, so far, at least, as English natural histories are concerned, in the mode of treatment of his subject, and the work ought to prove invaluable to all teachers of "nature-study." The illustrations—both coloured plates and text-figures—are in many cases excellent, some of them depicting the animals in attitudes or actions connected with the subject of the text. Examples of this type of illustration are afforded by the figure of a secretary-bird beating down a snake with its wings and beak, and that of a chamæleon darting its tongue at a fly.

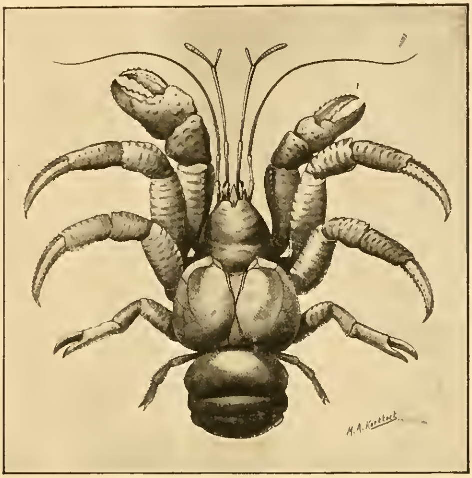

FIG. 1.—Cocoa-nut Crab (*Birgus latro*). From Davis's "Natural History of Animals."

In the first of the two half-volumes before us, the author commences by treating of the food of animals and the structural modifications of the animals themselves in correlation therewith, a subject which occupies the whole of one of the fasciculi and part of the other. This part of the subject is divided into three sections, according as to whether the diet is of an animal, vegetable, or mixed nature, each main group being taken in serial order in the several sections, commencing with mammals and finishing with zoophytes and sponges. Animal defences forms the title of the next main division of the subject. Here protective coloration and colour changes, mimicry, and the reason why so many animals are nocturnal, are discussed at length, and in the main satisfactorily, although all the latest observations on the former part of the subject are not mentioned. Passive defence, as exemplified by dermal armour, shells, the rolling-up habit, and the death-feigning instinct, and then active defence receive in turn their due share of attention, the second half-volume ending with an excellent dissertation on the various forms of animal respiration.

Unfortunately, the general excellence of the book is somewhat marred by certain blemishes. Confining our criticisms to a single group of animals, we have in the dental formula of the cat on p. 7 the number of pairs of incisors given as two instead of three. Nor can this error be attributed to the printer, for, although the total number of teeth in the animal is rightly given as thirty, the incisors are referred to in the text (as well as in the formula) as being eight, in place of twelve, in number. Moral, in proof-reading always add up your dental formula. Again, in the explanation of the figure of the dentition of the thylacine on p. 16, it would have avoided liability to error if the number of upper incisors had been alluded to as *four pairs* instead of *four*. Perhaps it is a venial error to perpetuate (p. 9) the old idea that the coloration of the tiger is designed solely to harmonise with an Indian grass-jungle, but it shows a decided want of acquaintance with modern zoological work to allude

FIG. 2.—Gila Monster, or Arizona Poisonous Lizard (*Heloderma suspectum*). From Davis's "Natural History of Animals."

[1] "The Natural History of Animals." Half vols. iii. and iv. By J. R. A. Davis. (London: Gresham Publishing Co., 1903.)

to the aard-wolf (p. 15) as a solely South African animal. More serious is the repetition of the error that blue foxes are the summer representatives of white foxes (p. 19), both being, as a matter of fact, in the winter coat. In our notice of the first two parts, we directed attention to a discrepancy between the lettering of some of the coloured plates and their descriptions; the same thing occurs in the plate of the polar bear facing p. 20, the animal being called *Ursus arctos* in the one place and *U. maritimus* in the other. Finally (p. 172), Euelephas is not the generic name for the Indian elephant, while there is no sort of justification for alluding to the polecat (p. 289) as *Putorius ermineus*, and the weasel (p. 290) as *Mustela vulgaris*, both animals belonging to the same genus, whether this be called by the one name or the other.

As samples of the better class of illustrations in this volume, we reproduce the figures of the cocoa-nut crab (Fig. 1) and of the "Gila monster," or Arizona poisonous lizard (Fig. 2). R. L.

NOTES.

THE American Academy of Arts and Sciences has, says *Science*, elected Dr. Joseph Larmor, F.R.S., as foreign honorary member in succession to the late Sir G. G. Stokes.

THE eighty-fifth session of the Institution of Civil Engineers was opened on Tuesday, when Sir William White, the new president, delivered an inaugural address of great importance, in which he discussed the main lines of recent advance in ship construction, the present conditions of British shipping and ship-construction, and warship building since 1860.

IT is announced by the *Electrician* that this year it is proposed to award the Nobel physics prize to Signor Marconi, the chemistry prize to Prof. Arrhenius, and the medicine prize to Prof. Finsen. Each prize is worth about 8000*l*.

THE United States National Academy of Sciences will hold its autumn meeting in Chicago, beginning on November 17.

WE regret to learn of the death on September 24 of Mr. J. A. Brown, aged seventy-two. He was an enthusiastic collector of flint implements, and author of a work entitled "Palæolithic Man in N.W. Middlesex" (1887).

A REUTER telegram from Stockholm states that Baron E. Nordenskjold has arranged to make a zoological and anthropological expedition to the frontiers of Peru and Bolivia. The expedition will start at the end of December or the beginning of January.

REFERRING to the suggested existence of radium in the sun, a correspondent points out that not a single line in the ultra-violet spectrum of radium described by Sir William Crookes (*Proceedings* Roy. Soc., vol. lxxii., No. 482) coincides exactly with a solar line. "The strongest radium line in Sir William's list is 3814·661, which is very near the solar line 3814·671 assigned to iron and carbon, but is not coincident with it."

THE *Terra Nova* and the *Morning*, the vessels which are to go to the relief of the Antarctic expedition on board the *Discovery*, have arrived at Hobart. The two vessels will leave together in the first week of December. The Swedish ship *Frithiof*, which is going to the relief of Dr. Nordenskjold's Antarctic Expedition, arrived at Buenos Ayres on October 30.

AT the end of last session it was decided to hold the meetings of the Physical Society alternately in the afternoons and evenings, and to change the place of meeting from the Chemical Society to the Royal College of Science, where the facilities for experimental demonstration are very complete. The first evening meeting will be held on Friday, November 13, at 8 p.m., when Sir Oliver Lodge will describe and illustrate by experiments (1) means for electrifying the atmosphere on a large scale, and (2) an arrangement for driving mercury pumps.

THE Paris correspondent of the *Times* states that the Sanitary Conference has at present under its consideration a project for the creation of an international sanitary bureau for the collection of information respecting infectious diseases, such as plague, cholera, and yellow fever, and also for the harmonious working of those sanitary regulations in the East which have so greatly contributed within the last five years to the preservation of public health as well as to the benefit of trade by the suppression of the old quarantine system. The international sanitary bureau would have its headquarters in Paris.

CAPTAIN J. M. JAMES, of Tokio, sends the following table showing the dates on which the first fall of snow took place on the summit of Fuji-Yama, the height of which in 1884 was 12,425 feet ±25 feet:—1884, October 6, light; 1885, September 27, light; 1886, October 7, light; 1887, October 2, heavy fall; 1888, October 1, heavy fall; 1889, September 25, heavy fall; 1890, October 4, light; 1891, October 12, heavy fall; 1892, September 25, light; 1893, October 7, heavy fall; 1894, September 22, light; 1895, October 3, light; 1896, September 21, light; 1897, October 5, light; 1898, September 26, heavy fall; 1899, September 16, heavy fall; 1900, September 25, heavy fall; 1901, September 25, heavy fall; 1902, September 19, heavy fall; 1903, September 27, heavy fall.

AT the recent meeting of the German Association at Cassel, Prof. Penck, of Vienna, was to have given an address on geological time, but illness prevented him from doing so, and his place was taken at the last moment by Prof. Conwentz, of Berlin. The writer of the article upon the meeting, in NATURE of October 15 (p. 586), was unaware that any change had been made, and the titles he gave of addresses for delivery on September 22 were those announced in the programme. Prof. Conwentz has now sent us a report of his address, which dealt with the preservation of remarkable natural objects, especially of rare living plants and animals. He pointed to the destruction of orchids in Thüringen, the extermination of rare thistles on the German coasts, the cleansing of brooks from aquatic vegetation, and the destruction of large trees, and argued that, both for scientific and æsthetic reasons, districts should be set aside where the natural features of the country should be preserved, while care should be taken not to destroy needlessly objects of interest to natural history.

IN a letter to NATURE of August 6, Messrs. Hutchins, of Cape Town, referred to the "Research on the Eucalypts Especially in Regard to their Essential Oils" by Messrs. R. T. Baker and H. G. Smith, reviewed in NATURE for April 2 (vol. lxvii. p. 524). The authors of this memoir have sent us a long letter of reply, in the course of which they say that the remarks upon their work are likely to lead to the idea that it has been confined to the chemistry of Eucalyptus oils almost entirely, and that new species have been named and a new classification for the Eucalypts formulated without sufficient warrant. They proceed to point out that their results are not those of the chemist

alone, but the joint efforts of a botanist and a chemist, and are supported by the field knowledge of botany of the botanical collector to the Sydney Technological Museum, and by numerous Australian authorities on the Eucalypts.

THE lecture on the "New Star in Gemini," delivered by Prof. H. H. Turner at the Royal Institution on June 5, has just been issued as an excerpt from the *Proceedings* of the Institution. Prof. Turner does not confine himself to his discovery of Nova Geminorum, but deals with the nature of new stars generally. He regards dark patches on the celestial sphere as not being actual voids in the stellar universe, but dark nebulæ which hide the light from stars beyond. A new star is due to the collision of a star with such a mass of invisible matter as this; for, adds Prof. Turner, "The friction of the encounter raises the temperature of the star enormously within a day or two, just as a meteor, on entering our tenuous upper atmosphere, is set ablaze in a second or two." This idea is, of course, fundamentally the same as that put forward several years ago in the meteoritic hypothesis as to the origin of new stars; and it is interesting to notice how the stone which the builders of astronomical theory rejected at that time has become the head of the corner since the phenomena of Nova Persei demonstrated the existence of masses of non-luminous matter in celestial spaces. But why did not Prof. Turner remember that Nova Persei only confirmed an explanation of the causes of the phenomena of new stars put forward long ago? He expresses anxiety lest England should fall behind in the progress of scientific discovery "for want of men and money, but especially men," and while we share his uneasiness of mind, his address gives rise to a wonder whether he knows what men have done, and are doing, for the advance of astronomy in this country.

THE Prussian Meteorological Institute (Berlin) has recently issued its report for the year 1902. This organisation deals especially with climatology, rainfall, and unusual atmospheric occurrences, while the Deutsche Seewarte (Hamburg) is chiefly occupied with marine meteorology and weather telegraphy. With the Berlin Institute is associated the meteorological and magnetical observatory at Potsdam, and the aëronautical observatory at Tegel. The latter establishment is carrying on a very valuable work in the investigation of the meteorological conditions of the upper air by means of kites and registering balloons, and has, since August, 1902, made daily ascents, the results of which are communicated by telephone to the Berlin office. On one occasion, in December last, a kite attained the unusual height of 5500 metres. These ascents are, in addition to the experiments with manned and unmanned balloons, undertaken in connection with the international monthly balloon ascents, to which we have had frequent occasion to refer. The magnitude of the useful work performed may be gauged from the fact that, including the observations from ordinary meteorological stations, rainfall statistics are received from 2574 places, and that no less than 37,273 reports were received from 1412 stations dealing especially with thunderstorms and unusual occurrences. The latter observations are published yearly in addition to the regular publications of the Institute, together with charts showing the place of origin, the tracks, and the velocity of the storms.

IN the *Annalen der Physik*, 10, Messrs. L. Holborn and F. Kurlbaum describe an optical pyrometer, first constructed in 1901, in which the temperature of an incandescent body is determined by photometric observations of the emitted radiations.

THE permanence of resistance standards of sheet manganese is discussed in the *Zeitschrift für Instrumentenkunde* by Mr. St. Lindeck, of Charlottenburg. Thirty-one resistances were experimented with from October, 1901, onwards; twenty-six of these were found to vary by not more than 0·05 per cent., and of the ten in which the variations exceeded 0·02 per cent., seven were large models which were subjected to currents of considerable intensity.

A NEW method of producing tension in liquids is described by Mr. J. T. Jackson in the *Scientific Proceedings* of the Royal Dublin Society (x., part i., 8). The method consists in the application to the particular question considered of the well-known principles governing the flow of liquid in a pipe of variable section. At a constriction the velocity increases and the pressure diminishes, and the author finds that under certain conditions the pressure can be made negative, thus confirming the well-known result according to which liquids may sustain a considerable tension without rupture.

DURING the past year several fragments of richly carved crosses have been found built into Lancaster Parish Church, which range from the earliest type of fine old Anglian work to late sculpture of the Danish period in the tenth and eleventh centuries. These most interesting relics have been described and figured by Mr. W. G. Collingwood in the current number of the *Reliquary and Illustrated Archaeologist*.

IN January, 1901, Mr. F. J. Horniman, M.P., gave his new museum and library, and the adjoining estate and the houses thereon, to the London County Council as places of public recreation and instruction; practically the only condition was that they were to be maintained in a proper state and dedicated to the public for ever. The London County Council has just issued its first annual report, which comprises a period of eighteen months. The report, which is illustrated, briefly states the history of the museum and of its transference, and gives a synopsis of the contents of the museum and of the scope of the library. The former arrangement of the museum has for the present been adhered to, and numerous descriptive labels have been prepared with the view of increasing the educational value of the museum. In the autumn term Dr. A. C. Haddon, F.R.S., the advisory curator, gave a course of lectures to teachers on the natural history of animals, which was illustrated by specimens in the museum and by lantern slides; owing to the large attendance it was necessary to give the lectures in a gallery; the average attendance at the lectures was 114. The total attendance at the museum for 1902 was 238,589, being an average of 658 on the opening days. The museum was visited by ninety-seven schools and institutions, with an average attendance of nineteen children. From these figures it will be seen that the educational advantages of the museum are appreciated, and there is every reason to believe that the next annual report will show that these are being increased. It may be added that the Horniman Museum and Library (at Forest Hill, S.E.) are open free to the public from 2 p.m. to 9 p.m. every day in the year except Christmas Day.

FROM the report of the Natural History Society of Northumberland, &c., we are glad to learn that the threatened split between that body and the Tyneside Naturalists' Field Club, to which allusion was recently made in our columns, has been avoided, and that for the future the two institutions are to amalgamate their forces.

IT is distinctly refreshing to find an American naturalist protesting against slavish adherence to the "fetish of

priority," as it is called by Dr. Gadow, in nomenclature, especially when there may be a doubt as to whether the names are really synonymous. In No. 76 (vol. xi.) of the zoological series of *Publications* of the Field Columbian Museum, Dr. D. G. Elliot directs attention to the use of the term Odocoileus for the American white-tailed deer and its relatives. That term was proposed by Rafinesque in 1832 for a fossil premolar of some kind of deer, which has been assumed to belong to the whitetail or some closely allied species. Even if this be really the case, Dr. Elliot doubts "whether a genus founded upon some fossil remains of an otherwise entirely unknown animal of a past age should be unhesitatingly adopted for a group of existing species that may be, in the majority of its characters, widely different from the extinct form." He further suggests the inadvisability of adopting palæontological names in any case for living forms, but adds that if such are used, the name Anoglochis, applied to European Tertiary deer, seems, as pointed out by Mr. Lydekker, to be available for the whitetail. It may be pointed out that, instead of giving a new name to the fossil deer-tooth, Rafinesque ought to have called it Cervus, and that by adopting Odocoileus we perpetuate an instance of ignorance and incapacity on the part of its proposer.

REFERENCE may be made to another change of nomenclature which, if adopted, is likely to cause the extreme of inconvenience with no resulting advantage. Almost from time immemorial the marmosets have been known as Hapale and the titi monkeys as Callithrix. In the October issue of the *Annals*, a well-known zoologist proposes to transfer the latter term to the marmosets (for which it appears to have been first employed) and to give a new name to the marmosets. In such instances, we venture to think, a "statute of limitations" should be insisted on. The replacement of well-established names is bad enough, but their transposition is unspeakable.

Two parts of vol. x. of the *Decennial Publications* of the University of Chicago are to hand. In the one Mr. A. C. Eycleshymer treats of the early stages of the development of the bony pike (*Lepidosteus osseus*), as observed in living specimens and preserved material. After treating this exhaustively, the author compares the phases with those of the few other living representatives of the enamel-scaled fishes, concluding with general remarks on the character and significance of yolk-cleavage. The view that similarity in the first four stages of cleavage indicates kinship between the bony pike and teleost fishes is not accepted. The second of the two is devoted to the results of a study of the development of colour and colour-pattern in beetles and in insects generally, by Mr. W. L. Tower. It appears that insects show two distinct types of coloration, the one —dermal (or cuticula) and hypodermal—as ancient as the group itself, and consisting of colours arranged in segmentally disposed spots and stripes, correlated with the deeper vital organs; the other, of much later origin, produced by scales, or modified hairs. This secondary type tends to suppress and obscure the original one, and, being developed independently of the vital structures, permits of much greater variation and diversity; it is, in fact, a purely ornamental type. The essential difference between the two may be realised by contrasting the sombre browns and yellows of the ground-beetles of the genus Carabus with the brilliant pattern of butterflies of the Vanessa group. Cuticula colouring (as shown in the beautifully coloured plate of beetles) commences in the fore part of the body, where the muscles first harden, and gradually spreads backwards. It is clearly connected with the hardening of the cuticula, which tends to become brown, hence the prevalence of browns and yellows in so many beetles and cockroaches, metallic tints in the former being due, of course, to another cause.

DR. WACE CARLIER and Mr. Lovatt Evans have made some interesting observations upon the so-called hibernating gland of the hedgehog (*Journ. Anat. and Physiol.*, xviii., part i.). This is of an orange colour when fully developed, but becomes deeper in tint as the winter sleep progresses, until, towards its end, it is almost black. It at first averages 1–2 per cent. of the body weight, rises by the second month to 2·7 per cent., and then gradually falls 1 per cent. towards the close of hibernation. Careful analyses show that, to commence with, the gland contains 40 per cent. of fat, and that this is reduced to 18 per cent. at the end of hibernation, the proteids during the same period showing a reduction of only 1 per cent. At the beginning of hibernation (October) the animals are exceedingly fat, but by the end of March all the fat stored in the tissues has disappeared. For the first month the weight of the hibernating gland falls rapidly, much fat being removed, but from then until the end of March there is little change, when again the gland loses weight owing to removal of its contained fat, and by the end of May it is completely exhausted and reduced to a mere fibrous cord. It would seem that life during hibernation is maintained practically upon fat alone, and that the hibernating gland is a store of fat reserved for this purpose.

WE have received No. 9, vol. i., of the *Scientific Roll* conducted by Mr. Alexander Ramsay. It deals with the bacteria, which are arranged according to their size, no other information being given than the name of the organism and its "size" position. We have already expressed the opinion that this list is an example of misplaced energy, because there is no such thing as a fixed size for a bacterium, the size varying considerably with alterations in the nutrient soil and other conditions.

THE problem of tracing out the connection of flowering plants with lower types must always possess attraction for botanists. In a number of the *Decennial Publications* of Chicago, Prof. Coulter has expressed the general views held by botanists that a similar line of development is probably not to be expected for monocotyledons and dicotyledons, and that neither of these groups are directly connected with the gymnosperms. The positive suggestion is made that the origin of flowering plants is to be traced to that group of ferns which is represented at the present day by Marattia and Angiopteris.

A GRAPHIC account of some of the curiosities of flora and fauna of the Auckland Isles and Campbell Island is given by Mr. L. Cockayne in the *Lyttelton Times*, wherein he relates the general impressions obtained during a short cruise in southern waters. Contrasts between the flora of these islands and that of New Zealand were observed in the brighter, generally purple or bluish tinge of colour, as compared with white or yellow tones which predominate in similar flowers found in New Zealand; this brightness is not associated with insect visitors, for they are wanting. Again, in New Zealand herbaceous plants rarely die down in winter, whereas in the southern islands many do so, but not owing to the cold, for the forests keep their summer aspect. On Adam's Island Mr. Cockayne had an opportunity of studying the nests of the albatross placed in exposed situations, where the solitary chicken remains on the nest for a year, and on the desolate Bounty Islands were found the nests of the mollyhawk, and numbers of animals, crustaceans, spiders and beetles which make their home in the guano or on the bare rocks.

DR. C. H. LEES wishes to make the following corrections in his account of the British Association discussion on the nature of the emanations from radio-active substances which appeared in NATURE of October 22. In the last line but two of the third paragraph on p. 611, "not yet found to be non-radio-active" should read "not yet found to be radio-active," and in the fifth line from the bottom of the column, "high velocities of the emanations" should read "high velocities of the radiations."

A SECOND edition, revised to June 30, 1903, of the "Student's Handbook of the University and Colleges of Cambridge" has been published by the Cambridge University Press. In addition to a few minor alterations the following important additions have been made to the book, viz. a complete list of university professors, readers, and lecturers, a list of lectures on honours subjects given in the university, and a statement of the set subjects for special examinations. The new regulations for the mathematical papers in the previous examination are also given.

THE first volume of administrative reports and the official reports of the meetings of the International Council for the Study of the Sea deals with the work of the year ending July, 1903, and has now been published by MM. A. F. Høst et Fils, of Copenhagen. The character of the work of this international council was described in our issue for September 3. The volume now published contains the main results of the work arranged by the council for the year dealt with, printed in both English and German.

THE second part of the "Botany of the Færöes," which is based upon Danish investigations, has now been published in Copenhagen by Det nordiske Forlag (London: John Wheldon and Co.). It was expected that this part, together with that published in 1901, would complete the work, but it has been found that a third volume will be necessary. Part iii. will contain papers on the vegetation of land and sea, and will, Prof. Eug. Warming says in a prefatory note, most likely be ready in a year or two.

AT the beginning of next year the firm of Gebrüder Borntraeger, Berlin, will commence the publication of a comprehensive review of progress in physical chemistry under the title "*The Physico-Chemical Review*: a complete international review of the sciences of physical chemistry and the allied branches of chemistry and physics." The magazine will be edited by Dr. Max Rudolphi, Darmstadt, with the cooperation of distinguished chemists and physicists in many parts of the world. The new journal is not intended to be a medium for the publication of original work, but a review of such work described in abstracts furnished, so far as possible, by the authors of papers. It is proposed to include English and French as well as German abstracts. The whole domain of general and physical chemistry, as well as the allied sciences on both sides, so far as they bear on physical chemistry, will come under review. Such an international review will prove of importance and value to practical men as well as to those engaged in the pursuit of purely scientific research. The review will be issued twice a month. Specimen numbers will be sent post free upon application to the publishers, Gebrüder Borntraeger, Berlin SW 11, Dessauer Strasse 29.

THE volume of *Transactions and Proceedings* of the New Zealand Institute for 1902 has been received. This is the thirty-fifth volume published by the board of governors of the Institute, and it is edited by the director, Sir James Hector, F.R.S. Copies can be obtained in this country from Messrs. Kegan Paul, Trench, Trübner and Co. It is impossible to refer to the contents of the sixty papers forming the *Transactions* part of this bulky volume. These original articles are divided into five sections, viz. papers dealing with zoology, botany, geology, chemistry and physics, and miscellaneous subjects. The thirty-fourth annual report of the New Zealand Institute precedes the next main division of the volume, which includes the proceedings of the various incorporated societies, viz. the Wellington Philosophical Society, the Auckland Institute, the Philosophical Institute of Canterbury, the Otago Institute, the Hawke's Bay Philosophical Institute, the Southland Institute, and the Nelson Institute. An appendix contains a tabulated report of the earthquakes in New Zealand during 1902, and seismograph records from different observatories throughout the country for the same year. The volume concludes with fifty-four well executed plates illustrating various papers included in earlier pages.

THE vacation number of the *Berichte* contains two papers on fluorescence. In the first of these Richard Meyer criticises Dr. Hewitt's theory that fluorescence is dependent on oscillatory isomeric change, and urges that a "fluorophore" group must also be present in the molecule. The paper by H. von Tappeiner on the action of fluorescing substances on ferments and toxins is a continuation of a research in which it was shown that fluorescent substances, which have little action on micro-organisms in the dark, become very poisonous in sunlight; thus a culture of Paramecium exposed to sunlight was destroyed in six to ten minutes by a trace of acridine hydrochloride which produced no effect in 100 hours in the dark; of the fluorescent substances examined only æsculin was without action both in the dark and in sunlight. The hydrolysis of starch by diastase is not affected by exposure to sunlight or by the addition of eosin, but if the solution to which the eosin has been added be exposed to sunlight, the yield of maltose is reduced from 76 to 21 per cent.; this retardation, which is only produced by a limited number of fluorescent substances, can be detected when the proportion of eosin is only one part in 400,000, but disappears entirely if the incident light is filtered through a layer of the fluorescent substance. The action of invertin on cane-sugar is also checked by the addition of eosin when the solution is exposed to sunlight, and the effect of one part of eosin in a million can be easily detected. Papayotin appears to be even more sensitive than diastase or invertin. The only toxin investigated was ricin; unlike the enzymes, this was destroyed by all the fluorescent substances examined with the exception of æsculin, but was not injured by non-fluorescent dye-stuffs or by fluorescent substances if kept in the dark.

A PAPER by Knoevenagel on the nature of the double-bond appears in the vacation number of the *Berichte*. In order to account for the conversion of butadiene, $CH_2:CH.CH:CH_2$, into dibromobutylene,

$$CH_2Br.CH:CH.CH_2Br,$$

he suggests that in compounds of this kind the carbon atoms are in a state of oscillatory motion, so that the molecule has, alternately with the formula given above, the structure represented by the formula

$$—CH_2.CH:CH.CH_2—.$$

Applying this theory to the benzene molecule, it is no longer necessary to assume a pendulum-like motion, as the carbon atoms may be regarded as revolving continuously, alternate atoms rotating to the left and to the right; the result of

this motion is that the three double bonds travel round the ring, whilst a labile form of the molecule with six free valencies is also indicated. In this way many of the peculiar properties of aromatic compounds may be accounted for.

THE additions to the Zoological Society's Gardens during the past week include a Sooty Mangabey (*Cercocebus fuliginosus*) from West Africa, presented by Mr. C. J. Spencer; a Levaillant's Cynictis (*Cynictis penicillata*) from South Africa, presented by Miss Bald; a Blue and Yellow Macaw (*Ara chloroptera*), a Red and Yellow Macaw (*Ara ararauna*) from South America, presented by General Sir Frederick Forestier Walker, K.C.B., G.C.M.G.; two Wharton's Fruit Pigeons (*Carpophaga whartoni*), a Christmas Island Dove (*Chalcophaps natalis*), five Christmas Island Crabs (*Birgus latro*) from Christmas Island, presented by Captain A. W. Cole; a Chameleon (*Chamaeleon vulgaris*) from North Africa, presented by Mrs. T. Wallis; seven Spiny-tailed Mastigures (*Uromastix acanthinurus*) from North Africa, three Brazilian Amphisbaenas (*Amphisbaena brasiliana*) from Brazil, an Indian Eryx (*Eryx johni*) from India, two Sharp-nosed Snakes (*Lioheterodon madagascariensis*) from Madagascar, deposited; six Black Swans (*Cygnus atratus*) bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE FORMATION OF THE POLAR CAPS ON MARS.—An interesting paper, by Mr. Percival Lowell, which deals with the manner of formation of the Martian polar caps is published in No. 2 of the Lowell Observatory *Bulletins*. Mr. Lowell observed the old polar cap on July 3, and found it to be diminishing; on July 5 it was only 20″ of arc in diameter, equal to a diameter of 48°.1 on the planet's surface; and shortly afterwards he noticed that a new, large, white deposit had formed, north of Arethusa Lacus and touching the Pierius-Callirrhoe, in longitude 345°. This new white patch extended from the old polar cap to about latitude 55° N., and the Pierius, which it crossed, could be seen running through it, thereby showing that the appearance was due to a deposit and not to clouds, which would have obliterated all the features equally; it also indicates that some kind of vegetation which had caused the deposit partially to melt, exists in the neighbourhood of the Pierius.

From July 7 to 17 the dark line of demarcation which usually surrounds the cap became less marked, until it was finally obliterated by the encroaching deposit of frost, only a superior whiteness, caused by the newly deposited frost lacking the sheen of the older, weathered and ice-welded snow, marking the presence of the older cap. It is only reasonable to suppose that this deposit actually was frost as we know it, for it is evident that a layer of frozen gas, such as solid carbon dioxide, would pass directly from the solid to the gaseous form under the pressure conditions obtaining on Mars, and would not exhibit the phenomenon of slowly melting such as was observed in the region about the Pierius.

The quick melting of the outer and the durability of the inner portion of the Martian snow-cap are both explained by these observations, which show that the whole cap consists of a perpetual kernel which periodically becomes surrounded by a shallow transitory husk, the formation of which was observed by Mr. Lowell.

The same observer also performed some experiments in connection with the visibility of the Martian canals, which showed that a wire having an angular width of 0″.60 at 1800 yards could be readily "glimpsed" with the naked eye, and from this he deduces that any canal having a width of half a mile on the planet's surface should be readily observable with a good telescope.

WOLF'S VARIABLE STAR 50, 1903, CYGNI.—A communication from Prof. Pickering to the *Astronomische Nachrichten* (No. 3911) states that the star recently announced by Wolf as being a probable nova appears on a large number of plates taken at Harvard between October 29, 1891, and the present time. On a plate exposed on July 30, 1895, the spectrum of this star is of the fourth type, and, from the series of plates, it is seen that the brightness varies by more than two magnitudes.

In the same periodical Prof. Wirtz records an observation made by him at Strassburg on October 15, when he found that the approximate magnitude of this object was 10.5, and that a comparison of its focus with that of several known stars on the Strassburg refractor showed no difference. The identity of this variable with the star B.D. +37°.3876 is confirmed by Prof. Wirtz.

PERIODICAL CHANGES IN THE COLOURS OF JUPITER'S BELTS.—In No. 3908 of the *Astronomische Nachrichten*, Mr. Stanley Williams directs attention to the periodical colour changes of Jupiter's equatorial belts announced in vol. lix. (p. 375) of the *Monthly Notices*.

The computed times of the maximum and minimum brightness of the respective belts are very uncertain, and Mr. Williams suggests that careful observations should be immediately commenced with the object of exactly determining the date when the red colour has entirely disappeared from the southern belt, and also the date of its corresponding reappearance, which will probably take place some time next year.

Mr. Williams's own observations indicate that the red colour has already almost entirely disappeared from this belt, some parts actually appearing blue, except in the neighbourhood immediately following the Great Red Spot, between longitudes 60 and 180, whilst the northern belt is of a bright, deep red colour.

THE MULTIPLE TAIL OF COMET 1903 *c*.—In discussing a number of beautiful photographs of Borelly's comet, which were obtained at Yerkes with a lantern lens having an aperture of 1·6 inches and a focal length of 6·3 inches, and are reproduced in the current number of the *Astrophysical Journal*, Prof. Barnard advances a novel explanation of the great changes of form which were observed in the tails of this and other comets.

From two photographs taken at Yerkes on July 24, the one immediately after the other, and one taken by M. Quenisset at Nanterre on the same date, it is seen that an enormous change in the form of the tail took place at about 2h. 30m. (G.M.T.), when a section of it broke away from the head and travelled in a retrograde direction at a rate, referred to the motion of the head, of about 29 miles per second. As the velocity of the comet itself was, at this period, about 22 miles per second *towards* the sun, it will be seen that the actual velocity of the section showed a repulsion of 7 miles per second *from* that body.

As an explanation of this phenomenon, Prof. Barnard suggests that either the outburst from the coma suddenly took place in a slightly different direction, or else the existing tail was forcibly detached by some unknown body (*e.g.* a swarm of meteorites) and simply floated away in its old path, under the sun's repulsion, until it was dissipated, or its light-emitting power died away; meanwhile, the new tail was formed by the material evolved by the coma, and for some reason the particles were evolved with a greater velocity than before, so that we get the phenomenon of the two tails nearly parallel for some distance, as shown on the Yerkes and other photographs.

THE SWISS ASSOCIATION OF NATURAL SCIENCES.

THE eighty-sixth meeting of the Société helvétique des Sciences naturelles was held at Locarno on September 2–5. Both as regards the number of visitors and the number and variety of the papers read, the gathering was highly successful. Several of the communications presented at the general meetings of the Association were especially well received.

M. A. Pioda (Locarno), the president for the year, after referring to the naturalists of the nineteenth century in his presidential address, went on to show that, in the same way as all other sciences have gradually been differentiated from

metaphysics, it was now the case with psychology. He spoke of the importance of this process as far as the increase of knowledge is concerned, and also as regards the improvement of each of the sciences and their relations one to another. He then traced the experimental and speculative character of psychology. Experimental psychology, the president urged, should confine itself solely to the scientific observation of facts. Certain facts, called psychical (Wallace, Crookes, Zöllner, Thury, &c.), are incapable of any explanation, at least by known physical forces, and it is the duty of science to examine these if psychology is really to assume an experimental character. The facts referred to belong, it may be, to psychophysics. When psychology has really become an experimental science such phenomena will be known not only by their external manifestations, but also by their hidden source, and the knowledge of them will become an organic whole.

Mr. E. Fischer (Bern) read a paper on the biological species of parasitic fungi and of the origin of new forms in the vegetable kingdom. The nature and properties of biological species were studied particularly in the Uredinées, and more recently in *Claviceps purpurea*. Philogenetically, at present, a common origin is attributed to the biological forms of a *species*; consequently, it seems plausible that the original form (Stammform) inhabits all the hosts on which its descendants now live, and that some at least among its descendants may be specialised on one or other of the nourishing plants. Reciprocally, the passage of one parasite to new hosts has been observed directly. Among the causes of the origin of biological species, following Klebalen, is admitted in the first line the direct adaptation (Anpassung und Angewöhnung) of these nourishing plants. It was also said that the explanation given is not applicable at present to the origin of species morphologically different; the morphological characters of species are, at most, partially attributable to the direct action of the nourishing plants (Näherpflanzen), and for the most part they must be related to the characters of the organisation in the sense used by Nägeli.

M. H. Dufour (Lausanne) took for the subject of his paper to the conference ten years' observations of solar radiation in Switzerland, and its diminution in 1903. The Swiss plateau on the north of the Alps (Lausanne, Bern, Zürich, Bâle) has a number of hours of sunshine varying between 1900 at Lausanne and 1200 at Bâle, that is to say, 47–44 per cent. of the greatest insolation possible. The maximum occurs in August (64–57 per cent.), the minimum in December or January (27–29 per cent.); in March and May the insolation is relatively feeble. To the south of the Alps (Lugano, Locarno) 2300 hours of sunshine were recorded, 59 per cent. of the possible maximum; two minima occur in May and November, and two maxima in July and February, with 60 per cent. At Alpine observatories the character of the results changes. At Davos (1500 m.) the insolation is not so strong in winter as in summer, when 1800 hours of sunshine are recorded; two minima are observed—in January and May—and two maxima (February and September–October). At the summit of Säntis (2500 m.) the insolation of winter, 45 per cent., exceeds markedly that of summer, 40 per cent. The mean amount is 42 per cent; the minimum occurs in May and June, and the maximum in November. For the intensity of the solar radiation, measured by Bührer (Clarens-Montreux) and Dufour (Lausanne), the result has been obtained of 8·5 calories (kilogram-degrees) per minute and per square metre of normal black surface on the sun between 11 and 1 o'clock. The maximum occurs in April–May, the minimum in January. At an altitude of 400–500 m. it rarely exceeds 10 calories, at 2000 m. (Rochers de Naye) 13 calories. In 1903 the values of the actinometric measures are notably feebler than in previous years, probably because of an abnormal opacity of the atmosphere, which may be attributed to the diffusion in the air of dust arising from the violent volcanic eruptions of the Lesser Antilles, which would facilitate the condensation of aqueous vapour in the form of fog—very attenuated and invisible, but yet absorbent.

M. P. Weiss (Zürich) exhibited by means of a series of interesting experiments the new magnetic properties of pyrrhotine, that is to say, the directions in which crystals of this mineral are sensitive to the influence of magnets.

M. A. Lang (Zürich), in speaking of the biological significance of elegance in certain marine organisms, said that the scientific study of animal forms did not prevent an understanding of the æsthetic manifestations of nature which could be applied in decorative art, for instance. He showed that all those characters which give beauty and charm to the marine fauna—such as form and symmetry, phosphorescence, and transparency—enable these animal forms to respond to their environment, and thus to facilitate and assure their continued existence.

The number and importance of the communications which dealt with the canton of Ticino were very remarkable. M. C. Keller (Zürich), with his descent of the animal world of the Ticino cantons showed that the fauna principally studied by Stabile and Pavesi contains very different elements; the lacustrine is a *fauna relicta* (Pavesi), and the terrestrial contains arctico-alpine elements. But the most remarkable characteristics are those of the sylvatic fauna of central Europe, and also the great number of types of the Mediterranean subregion. He also made several interesting comparisons with the fauna of other Swiss regions, and showed several new researches for Ticino which have been found by him. At the same meeting M. F. Merz (Bellinzona) spoke on the forestry of the Ticino canton, and similar questions were referred to in various sections by MM. Freuler, Bettelini, Calloni, and Pometta.

The most largely attended sectional meetings were those concerned with physics and chemistry, and the most important papers read at these meetings were those of MM. Haller (Paris), Schär (Strassburg), de la Rive (Geneva), Nölting (Mülhouse), Forel (Morges), Bertoni (Livorno), Tomasina, Soret (Geneva), Schühmacher-Kopp (Lucerne), Riggenbach (Bâle), Hagenbach (Bonn), and others.

In the botanical section the most interesting communications were those of MM. Rikli (Zürich), C. Schröter (Zürich), A. Usteri, and Wilezeck (Lausanne); in the zoological section a magnificent monograph was presented by the honorary member, M. P. Pavesi (Pavia), on the fauna of the valley of Aosta, and papers were read by MM. Lang, Keller, Studer (Bern), Volz (Bern), and Pictet (Geneva); the section of geology and mineralogy mustered but a very small attendance, for the Swiss geologists were almost all at the international congress at Vienna.[1]

The excursions and the receptions, which took place in exceptionally fine weather, the cordial welcome and generous hospitality of the residents, all contributed to the splendid success of this year's gathering. R. NATOLI.

THE NATURE-STUDY EXHIBITION.

THROUGH the kindness of the Civil Service Commissioners and His Majesty's Office of Works a Nature-Study Exhibition was held at Burlington Gardens from October 30 to November 3. In the absence of Lord Avebury, chairman of the committee, Sir Henry Howarth presided, and Sir John Cockburn declared the exhibition open.

It may at once be said that the object of the undertaking was to put into effect, forthwith, the lessons learned from the exhibition held last year at the Royal Botanic Gardens. There, through the energy of Mr. J. C. Medd, for the first time were brought together all the various methods and matters which have been taken or mistaken for nature-study. It soon became obvious that much excellent science teaching on the one hand was masquerading under the title, and on the other that desultory collecting without rhyme or reason was a second claimant for it.

At the suggestion of Mr. Wilfred Mark Webb, honorary secretary of the Middlesex Field Club and Nature-Study Society, delegates from it and from the Selborne Society met to appoint a committee to organise an exhibition on definite lines. The area from which exhibits were invited was also restricted to a dozen or so counties within easy reach of London. Evidence of work was asked for which dealt with such observational teaching as should form part of the education of all. This, while serving as an excellent preparation for science, is scientific only as regards method and accuracy of treatment.

[1] The communications to the various meetings of which mention is made will appear in the *Actes* and the *Comptes rendus* of the Association, most of them *in extenso*. Thanks are due to MM. Pioda, Fischer, Keller and Dufour for information very readily given.

The exhibition has been exceedingly successful from an educational point of view, and the exhibits showed that the schools which contributed had entered into the spirit which guided the committee in the preparation of its prospectus and in the desire to demonstrate what nature-study really is.

The judges were Miss Hodgson, formerly of the House of Education, Ambleside; Mr. Jonas Bradley, famous for his outdoor school at Haworth, Prof. Haddon, Prof. Minchin, and Dr. Chalmers Mitchell. The awards were made in strict accord with the objects of the committee, and were given so as to mark the work of the schools which are on the right lines. Certificates of merit, the highest official award of the committee, fell to the lot of the Froebel Institute, Streatham High School, Dulwich High School, Queenswood School, Orlestone Board School, and the Training College for the Deaf, Fitzroy Square.

Not the least important part of the proceedings were the conferences, at which practical teachers not only described their methods, but also in some cases showed how they came to adopt them. Speakers were carefully chosen from among those who exhibited last year and whose work was well known to the executive committee, of which several members helped to organise the previous effort.

On the morning of Saturday Mr. Hedger Wallace, chairman of the executive, presided over a meeting at which Mr. Badley, of Bedales School, Mr. Harry Lowerison, of the Ruskin School Home, Miss Sillham, of the Froebel Institute, and Miss Ethel Webb, of Streatham High School, spoke. In the afternoon the chair was taken by Mr. Jesse Collings, who had something to say about the Bill which he has before Parliament to promote nature-study in elementary schools, more particularly with the view of improving our agricultural education. There is every hope, moreover, that his measure will be passed without opposition. During the afternoon Miss Alderton, of Stretton, Mr. Thomas, of Orlestone, and Mr. Dodgeon, of Burnley, described their work. In the evening Mr. Richard Kearton, who has done so much to change the taking of birds' eggs for the collection to the taking of them by the camera, showed the pick of his well-known studies of wild-life, and others that had not been seen on a screen before. Afterwards, as on the previous evening, Mr. Martin Duncan proved the great possibilities of the Urban Duncan micro-bioscope for recording natural history observations in the ordinary way and under the microscope.

On Monday Mr. Oliver G. Pike gave an illustrated lecture on birds in their homes, and later the Middlesex Field Club held a meeting. Mr. Hedger Wallace pointed out the great necessity for a field club which should deal with Middlesex, record the fast disappearing animals and plants, and organise a local museum. Mr. Henry Stevens showed a number of remarkable slides of animals and plants under control, and Mr. Wilfred Webb demonstrated, also by the aid of the lantern (kindly lent by the Royal Geographical Society), how much nature-study could be done in London, proceeding afterwards to touch on the work of schools throughout the country.

On Tuesday evening Mr. R. B. Lodge lectured on some suburban birds and beasts, while under the auspices of the Selborne Society Prof. Boulger and Mr. E. A. Martin spoke on subjects in character with the objects of the exhibition. Financially, also, the exhibition has been a success.

BOTANY AT THE BRITISH ASSOCIATION.

THE meetings of the botanical section at Southport showed no falling off in interest. The arrangements made by the local authorities were admirable, and there was a good attendance of British and foreign botanists.

In his presidential address, Mr. A. C. Seward, F.R.S., gave an able and comprehensive summary of the present state of our knowledge concerning the composition and distribution of the floras of the past, from the earliest records in the Devonian and Lower Carboniferous up to the dawn of the Cretaceous period.

The report of the joint committee of Sections K and L on the teaching of botany in schools was read and discussed. A summary of the recommendations will be found in the report of the education section. In an interesting discussion which followed the reading of the report in Section K, several botanists expressed their approval of the report, and it was suggested that it would be a good plan if the methods recommended could be tried by teachers and the results communicated to the committee.

The morning of September 11 was given up to a series of papers and a discussion on the subject of heredity. Mr. W. Bateson, F.R.S., in an introductory address on recent discoveries in heredity, gave an excellent account of Mendel's researches, and pointed out that we have now reached a stage at which, by the employment of these methods, the solution of problems in heredity becomes possible under certain conditions. He described many of his own experiments, and exhibited specimens of the results which he had obtained in the hybridisation of various species of plants and animals, all of which give strong support to Mendel's laws.

Miss Edith R. Saunders followed by an extremely lucid account of her recent work on cross-breeding in plants, and showed the results of some of her more striking experiments (*vide* Reports to the Royal Society, 1902).

Mr. C. C. Hurst read a paper on recent experiments in the hybridisation of orchids, in which he showed by means of some beautiful coloured drawings that, so far as the intermediate hybrids are concerned, the results are apparently consistent with Mendelian principles. Dominant hybrids are infertile, and in the case of false hybrids further research is necessary before any definite conclusions can be arrived at.

The morning of September 14 was devoted to a discussion on the origin of the Monocotyledons, introduced by Miss Ethel Sargant, whose work on this subject is well known (*vide* "Annals of Botany," 1903). Miss Sargant maintains that a careful study of the anatomy of seedlings in various families of Monocotyledons and Dicotyledons leads to the conclusion that the common stock from which they both spring was not only angiospermous in character, but that it was more like a Monocotyledon than a Dicotyledon.

Miss E. N. Thomas, who followed with a paper on the structure of the embryo sac and the phenomena of fertilisation, pointed out that the results obtained support Miss Sargant's view in so far as they indicate the existence of a great gulf between Angiosperms and all other groups of plants, whilst there is little, if any, distinction in these respects between Dicotyledons and Monocotyledons.

In the subsequent discussion Miss Sargant's views were freely criticised, but all the speakers agreed that this valuable contribution to a very difficult question opened up a very interesting field of investigation.

Prof. H. Marshall Ward, F.R.S., gave an account, illustrated by plans and lantern slides, of the new botanical laboratories at Cambridge. This large block of buildings provides ample accommodation for study in all departments of botany, and special facilities are afforded for original investigation. The university is to be congratulated upon so important a development of its botanical school. Prof. Lignier presented a paper on the flower of the Gnetaceæ, in which some interesting new facts were brought forward, and Dr. Lotsy gave an account of his work on parthenogenesis in *Gnetum ula*.

The semi-popular lecture was given on the afternoon of September 14 by Prof. J. B. Farmer, F.R.S., on stimulus and mechanism in organisation. In a very able address the lecturer discussed the various forms of stimuli and the nature of the processes involved, and endeavoured to trace a connection between the growth and structural differentiation of an organism and the response to definite stimuli acting on special kinds of mechanism.

On September 12 an excursion, under the leadership of Mr. Lomax, was made to the Clough Foot Colliery, and on Tuesday afternoon the vegetation of the sandhills was investigated under the leadership of Dr. Otto v. Darbishire and Mr. Henry Ball. In a paper which he had previously communicated to the section as a preliminary to this excursion, Dr. Darbishire pointed out that the sand dunes are encroaching on the grass land, and that, although they can be fixed by sand-loving plants, it is only temporarily, and psamma is commonly planted for this purpose. The plant societies in the various regions of the dunes are well marked, and include a number of extremely interesting

plants, one of which, *Pyrola rotundifolia*, var. *maritima*, is found in certain parts in great profusion.

Of the numerous other papers communicated to the section, reference can only be made to some of the more important.

Fungi.—Mr. B. T. P. Barker (Cambridge) gave an account of the ascocarp in Ryparobius. The ascogonium appears to be uninucleate at first, and immediately after contact with the antheridial branch contains two nuclei, either situated closely together or apparently fusing. Later most of the cells of the system of hyphæ, developed from the ascogonium, are uninucleate, but some contain two nuclei, which probably fuse and become the single nucleus of a young ascus. Associated closely with this single nucleus is a structure of variable shape which has almost as strong an affinity for stains as the chromatin of the nucleus itself. It appears to be of the nature of a vacuole and to be intimately concerned with the nutrition of the nucleus, which at this time is of a remarkably large size. The results obtained point to a close relationship between the genera Ryparobius and Thelebolus.

Mr. E. S. Salmon communicated the results of culture experiments with biologic forms of the Erysiphaceæ, which prove that under certain conditions a "biologic form" which in nature is restricted to the species of a certain genus of host-plants becomes capable of infecting species belonging to another genus, and species of plants which are immune in nature are able to be infected. The author considers that it is possible that in this change of infection-powers of biologic forms of parasitic fungi in consequence of injury to the host-plant an explanation may be found of the sudden appearance of disease on plants hitherto immune.

Prof. H. Marshall Ward, F.R.S., in a paper on Eriksson's mycoplasm hypothesis, showed by means of a series of microphotographs and drawings that this so-called mycoplasm consists of haustoria only, and that there are no grounds for believing that Eriksson's views are well founded.

Prof. T. Johnson communicated a short note on a willow canker which has been the cause of considerable damage in an osier holt in the west of Ireland.

Physiology.—Prof. Letts and Mr. J. S. Totton contributed a valuable paper on the occurrence of *Ulva latissima* and *Enteromorpha compressa* in sewage effluents, and on variations in the composition of the tissues of these and allied seaweeds. The view expressed by one of the authors in conjunction with another chemist, that the growth of *Ulva latissima* in quantity in a given locality is a sign of sewage pollution, has received remarkable confirmation by the occurrence of this seaweed and of *Enteromorpha compressa* in the Belfast sewage beds. The spores probably found their way into the sewage by leakage of sea water into the system. The percentage of nitrogen was found to be higher, especially in Enteromorpha, in the sewage specimens than in those taken from the sea or brackish water.

Mr. R. H. Yapp gave an account of his observations on fruit-dispersal in *Adenostemma viscosum*. This plant is a composite which is widely distributed in the warmer regions of the globe. The distribution of the fruit is brought about by a pappus which consists of stalked glands, composed of numerous capitate hairs, which secrete a copious viscid fluid. The movements of the pappus setæ are effected by a group of motor cells which forms a pulvinus at the base of the stalk of each gland.

Mr. Harold Wager described some experiments on the staminal hairs of *Tradescantia virginica*, from which it appears that the protoplasmic movement can continue for some days after the hairs are removed from the plant, even if they are completely embedded in vaseline. The author also described a method by which the nucleus of the cells can be stained by means of the coloured cap contained in the vacuole.

Mr. J. Parkin gave an account of his work on the localisation of anthocyan in foliage leaves. In young leaves, and in the autumn coloured leaves, the anthocyan is usually confined to the mesophyll; in mature leaves mainly to the epidermis, except when the colouring matter is only produced under exceptional conditions, when it is usually found in the mesophyll. The author concludes that the presence of anthocyan in the mesophyll seems to weaken somewhat the view that its function is to protect the chlorophyll by absorbing the destructive solar rays.

Anatomy and Cytology.—Miss Ethel Sargant and Miss Agnes Robertson read a paper on some anatomical features of the scutellum of Zea Maïs. They find that the epithelium of the scutellum in contact with the endosperm becomes folded into a number of gland-like structures in which traces of some kind of secretion are commonly found.

Mr. Arthur W. Hill (Cambridge), in a paper on the histology of the sieve tubes of Angiosperms, showed that the sieve plates of the mature sieve tubes are traversed by relatively thick slime strings, each being enclosed in a callus rod. In the radial and tangential walls the slime strings, which are grouped into oval or rounded pitted areas, are much smaller than those in the sieve plates, and some three to six strings are enclosed in a callus rod. Connecting threads also occur between the sieve tubes and companion cells. Between the sieve tubes and cambiform cells, and between the latter and the companion cells, the small groups of threads are found in small and deep pits.

Mr. J. Lloyd Williams (Bangor) read a paper on the alternation of generations in the Dictyotaceæ and the cytology of the asexual generation, in which he pointed out that the nuclei of the tetraspore plants have about thirty-two chromosomes, and that in the formation of the tetraspores these become reduced to sixteen. The sexual plants also have the reduced number. The evidence, therefore, shows that the tetraspore produces a sexual plant, whilst the oospore produces the tetraspore generation.

Mr. L. A. Boodle (London) communicated a short paper on the structure of leaves of bracken from different habitats. In a very exposed and sunny situation the leaves are hard and short, while in a well sheltered and shaded locality they are much larger and soft. Long sori and short sori are typical of the first and second situation respectively. The internal structure of the pinnules varies with the habitat in a corresponding manner; the presence of a continuous, or nearly continuous, hypoderm and the large amount of the palisade tissue formed distinguish the leaf of the exposed from that of the sheltered plant.

Ecology, Distribution, &c.—In addition to Dr. Darbishire's paper on the sandhills of Southport, several other papers of some interest were read in this section. Miss M. C. Stopes gave an account of the colonisation of a dried river-bed. The stream became dried up in April, 1901, and during the years 1901–1903 observations were made upon the plants found growing on the dried up mud. In 1903 these included eleven frequent semi-aquatics, of which four are locally dominant, and thirty-two frequent land plants, of which eight are locally dominant.

Mr. T. W. Woodhead (Huddersfield) described his methods of mapping the distribution of plants, and the anatomical variations produced in the leaves of certain plants grown under varying conditions in different plant societies. He showed clearly by means of photographs what striking variations may be produced in the undergrowth of a wood owing to the nature of the trees immediately above it.

Dr. F. F. Blackman (Cambridge) gave an excellent summary of modern views on the phylogeny of the Algæ, illustrated by diagrams.

Mr. A. W. Hill (Cambridge) gave an account of his recent expedition to Upper Peru, and Mr. W. Wilson communicated a list of some of the plants growing on the serpentine rocks of the north-east of Scotland.

Fossil Plants.—There were only two papers of any importance in this section. Mr. E. A. Newell Arber (Cambridge) communicated some interesting observations on homœomorphy among fossil plants. Among recent plants species of different descent may possess many closely identical characters as the result of adaptation to particular conditions of the environment. There is some reason to believe that similar cases may be found among fossil plants, and the author finds some ten genera and species in which this phenomenon occurs.

Mr. Seward communicated a paper by Dr. D. H. Scott, F.R.S., and Prof. F. W. Oliver on the seed of Lyginodendron, which was illustrated by some beautiful lantern slides.

Economic Botany.—Mr. E. T. Scammell read a paper on the forest resources of Australia available for British commerce. The forest areas of Australia comprise 107,037,000 acres of marketable timber, or nearly half the areas of the forest lands of Europe, excluding Russia. The timbers are

of many varieties, and some of them are of high commercial value. The chief of these are the eucalypts, of which there are more than 150 species. Besides the eucalypts there are many kinds of casuarinas (the Australian oak), some conifers (the Moreton Bay pine, the cypress pine, the brown pine, or colonial deal, and others), many acacias (the Australian wattle), Banksias, and numerous other varieties. The range of Australian wood at present available for British commerce is limited. Western Australia and Tasmania are the only States that have seriously dealt with the question of exporting timber or of using their forest resources as a valuable commercial asset.

Mr. W. Powell described a process for seasoning and preserving timber which appears to be at once simple and effective. The timber is treated with a dilute solution of sugar, in which it is boiled until the air in the interstices has been got rid of. The timber is then cooled and dried at a fairly high temperature. Timber treated in this way is much improved, the soft woods especially, both in hardness and toughness.

EDUCATION AT THE BRITISH ASSOCIATION.

THE educational science section has become the debating ground where educational principles can be discussed without reference to minor administrative details and class distinctions. Increased efficiency is the leading idea, and it is promoted by the expression of authoritative opinion from a platform of the British Association. Attention is there directed to matters requiring consideration by authorities responsible for educational work, and the directions in which progress can be most usefully made are afterwards indicated in reports presented by committees. The work of the section is thus both critical and constructive, and its sphere of influence increases in extent every year.

After the president's address on the morning of September 10, a discussion on school curricula was carried on throughout that day and the next. The material for discussion consisted of eight papers received from leading representatives of various branches of educational work in response to an invitation issued by the committee of the section. The papers were printed in full in the September number of the *School World*, and the authors are Prof. J. Adams, Prof. H. E. Armstrong, F.R.S., Miss S. A. Burstall, Mr. G. F. Daniell, Mr. W. C. Fletcher, Mr. T. E. Page, Mr. J. L. Paton, and Prof. Michael E. Sadler. The three main divisions of the subject were:—(1) General principles upon which a school curriculum should be constructed; (2) the education of girls; (3) commercial education. To concentrate attention upon specific points, several propositions were formulated, and the authors of the papers were asked to speak to them instead of reading the papers. The propositions which were laid before the meeting during the discussion, and received general assent, were as follows:—

(1) It is desirable that specialisation should be deferred to as late a period as possible in the school career, and that the early curriculum should be so arranged as to lay a good foundation in English subjects, with, say, drawing and elementary science.

(2) It is to be regretted that the influence of public school entrance and scholarship examinations encourages the premature devotion of too much time to classics; it would be desirable that the study of Latin should not be taken before, say, twelve years of age, and that the language teaching up to that time should be confined to the mother tongue and one modern language.

(3) That a large measure of practical instruction should be included in the school course, and that both literary and practical instruction should be given throughout and made interdependent.

(4) It is desirable that in organising the curriculum there should be some differentiation, especially in science, between courses of study for boys and those for girls, more particularly between twelve and sixteen years of age.

(5) That for all girls literary instruction is of the highest importance; at some period of their school life practical instruction in the domestic arts should be provided, based on and correlated with elementary science teaching.

(6) With the view of obviating over-pressure, injury to health and superficiality, girls who intend to proceed to college, or enter a literary profession, should in general remain at school until eighteen years of age.

(7) It is desirable that county and borough councils and other authorities offering scholarships for girls to enable them to proceed to college should not expect them to take up their scholarships before they reach the age of eighteen.

It is impossible to describe in a few words the many important opinions expressed in the papers and during the discussion, but there was general agreement that the development of intelligence and self-reliance is of prime importance. The discipline of scientific studies was generally recognised, and also the necessity of making courses of instruction more practical than hitherto; that is to say, pupils should be active rather than passive in their attitude towards knowledge.

This is the touchstone which will test the quality of all educational work, whether in the humanities or in science, but as science deals with things more than words, it has special claims for recognition in the school curriculum. Mr. Balfour a short time ago, in referring to the relative advantages of classics and science as school subjects, expressed himself as doubtful whether scientific studies could supersede with advantage the traditional course of classics in schools. In connection with his remarks, it is of interest to refer to the following statement made by Mr. A. C. Benson in the *School World* for October in continuation of the discussion on curriculum:—"I have taught classics at Eton for nearly twenty years to boys of every degree of capacity. I have found that as a basis for teaching able boys they are excellent. But the effect of the present crowded curriculum, with classics as the basis, upon boys of ordinary or limited capacity is so absolutely negative, from the educational point of view, that I should hold that it would justify almost any experiment being tried."

Here we have an acknowledgment by a teacher of exceptional experience and ability of the failure of classical instruction so far as the average boy is concerned. This in itself is sufficient to justify the plea of the reformer for a readjustment of school studies on a broader basis than that at present adopted. In the discussion on curriculum, Mr. T. E. Page, a representative of literary culture, asked what branch of natural knowledge men of science wished to be taught in schools, and urged that there was a diversity of opinion upon this matter. The answer is, of course, that the subject is not so important as the method. It matters little whether botany, physics, chemistry, or any other science subject is used as the basis of instruction provided that they are studied practically under encouraging conditions and in the spirit of scientific inquiry. What men of science urge is that scientific studies are capable of forming habits of mind—resourcefulness, perspicacity, enterprise and initiative—in a way which the traditional courses and methods have not accomplished in the past.

A general view of the work done by the late Dr. Gladstone in connection with the teaching of science in elementary schools is contained in the final report of the committee on that subject. The committee was first appointed in 1878, with Mr. Mundella as chairman and Dr. Gladstone as secretary, and since 1883 has been annually reappointed to continue inquiries on the subject then instituted. The chief work of the committee has been to watch and record the proportion of children examined in science subjects in elementary schools. There has, of course, been a decided increase in numbers, but when the character of the work which has been done is considered, the committee now reports that the progress made is undoubtedly unsatisfactory. It is beyond question that science has in no way taken its proper place in our system of elementary education. Here and there work of the very greatest value has been done, but such cases are all too rare.

The report concludes with the remark that, in view of the national importance of developing the scientific spirit in elementary schools, it is not too much to say that it is now the duty of the Association to intervene with constructive proposals which will promote such an object. Judging from the great success which has attended the labours of the committee on the teaching of chemistry in schools and the recent discussion on the teaching of mathematics, there can be little doubt that a general inquiry might now be undertaken with great advantage, and that proposals might be made which would be of the greatest value

in guiding educational authorities generally. A special committee has therefore been appointed to report upon the courses of experimental, observational and practical studies most suitable for elementary schools, and generally as to the steps which it is desirable to take to secure proper attention to and encouragement of such studies. All who have paid attention to the subject will probably agree that some organised effort should now be made to extend the teaching of scientific method.

The dangers of ill-considered schemes of science study were referred to by Prof. H. E. Armstrong in presenting the report of the committee on the teaching of science in elementary schools, and were emphasised by Prof. Marshall Ward in the subsequent discussion. The committee points out that education authorities, realising the value of nature-study as a means of training and a matter of interest, will force instruction in this subject in schools in which the teachers are quite unable to handle it effectively by reason of their want of scientific training and knowledge. It cannot be too strongly impressed upon the lay mind that unless nature-study is taken up as a subject by which the spirit of scientific inquiry is created and fostered, men of science have no sympathy with its introduction into schools.

The report on the teaching of botany in schools should do something to direct the nature-study movement along scientific lines. There is a tendency to consider that the demands of the advocates of nature-study in schools are met by supplying reading-books in which a variety of facts in natural history are described, and are accepted by the pupils on the *ipse dixit* of the author or the teacher who dispenses them. If that is to be the result of the movement, it would be just as well to read fairy tales or fiction, so far as the development of mental faculties is concerned. To be of any value as a training in scientific method, nature-study must not only create interest, but must also demand active work for a definite purpose from the pupils. The difficulties in the way of doing this under the present conditions of teaching in schools are very great, but unless this fundamental principle of scientific instruction is acted upon, nature-study will prove a snare and a delusion.

On the importance of studying plants alive and experimentally, the botany report expresses decided opinion. It is pointed out that scientific curiosity is better occupied in discovering how plants get their food, respond to stimuli, adapt their structures to new circumstances, contend with their rivals or enemies, and propagate their race than in learning Latin names for the shapes of their leaves or classifying species. Individual practical work is, in fact, the only way to gain useful scientific experience, for knowledge accumulated by a mere act of memory is feebly grasped and soon forgotten. Throughout all stages of instruction, observation and experiment in the laboratory and out of doors must be the method of study. Among the conditions of profitable object-lessons for children, the committee notes the following :—(1) Every pupil should have an object to himself, or at least be able to examine the object as long and as closely as he pleases. A drawing is not to be allowed to rank as an object. (2) Living and growing plants should be frequently observed. (3) The living plant should not only be studied in flower, but whenever the change of season brings on a new phase of growth. Fruits, buds, and seedlings are as important as flowers. (4) Experiment can hardly come in too early, and there is nothing else quite so stimulating. Even young children can appreciate the interest of a simple experiment, and they may be allowed to take part in it before they are able to conduct it themselves.

Where botany can be seriously studied, plant-physiology is recommended as the basis of work, on the ground of its great practical importance and of its special value as discipline when studied systematically. The seedlings of common garden plants are recommended as providing the best material for early lessons.

A course of lessons on seedlings can be so arranged as to lead the beginner to consider attentively the nutrition of a green plant, the adaptation of the plant to external circumstances, and the development of new parts. The course should bring in drawing to scale, the graphical representation of experimental results, the care of garden beds, the care of water cultures, and many other practical arts. It ought also to encourage the habit of close observation, the habit of methodically comparing structures which in different plants answer the same purpose, the love of experiment, and the unwillingness (so characteristic of the scientific mind) to accept any conclusion except as the result of an independent and careful judgment.

How school gardens can be made of value in connection with the teaching of botany is described in one section of the committee's report by Miss L. J. Clarke, whose work at the James Allen's Girls' School, Dulwich, has shown that botany can be made a practicable as well as practical school subject. Other sections of the report are devoted to school excursions, collecting—which is condemned when carried on for selfish ends and without any scientific purpose—initiative of the teacher, and the simplicity of appliances required for teaching purposes.

An interim report was presented by the committee on the influence of examinations on school curricula and of schools on university requirements. The report was drawn up by the chairman, Prof. H. E. Armstrong, and consisted of expressions of opinion received from heads of schools, university tutors, &c., upon subjects to which their attention was invited. While pointing out the many evils which attend examinations, the majority of the persons who favoured the committee with replies took the view that in some form they are necessary. It is generally recognised that there has been a marked tendency to develop and improve examinations of late years. Among other results of the inquiry the following are noteworthy :—The effect of specific examinations, both as affecting general training and as encouraging undue specialisation, either on the humanistic or on the scientific side, was considered to be bad in most cases. Opinion was practically unanimous as to the need of unifying examinations with the object in view, among others, that certain examinations may serve a common purpose, *e.g.* as qualifying examinations for entrance upon a course of professional study.

The need of preventing examinations from becoming stereotyped and behind the times, and thus discouraging the development of new or improved methods, was another subject submitted for opinions, and the replies expressed the general desire that examiners should confer with teachers in some organised way.

With regard to the possibility of arranging outside examinations so as to test what has really been taught in the school, leaving the teachers a freer hand than in the past and arranging for their cooperation on the examining board, in the setting of the questions, and in considering the answers, there appeared to be a strange disinclination to insist that the teacher should be trusted.

The extent to which certain subjects are to be regarded as necessary and others as optional evoked diverse expressions of opinion, and the general conclusion seemed to be that entrance examinations at Oxford and Cambridge do not tend to promote a good all-round education.

The report of the committee on the conditions of health essential to the carrying on of the work of instruction in schools consists almost entirely of two reports of subcommittees on (1) the essentials of school buildings; (2) eyesight in school children. The report of the subcommittee on the former subject forms a condensed *résumé* of scientific principles of school construction of a very practical character. It may be regarded as a contribution toward the realisation of the proposal that a short practical treatise should be drawn up by the committee. Its conclusions are of a general character, and are applicable to all classes of school buildings. The subcommittee on eyesight in school children has dealt with and reported on (*a*) the causes of defective eyesight in school children, and (*b*) the conditions requisite for preserving eyesight from injury in school life. Besides dealing with general principles involved, it makes some practical recommendations of much importance. One of these is that it should be required that school books should be "passed" in respect to their typographic standard and quality by some recognised hygienic authority before being adopted in schools. The necessity for a very considerable eye-working distance in all the exercises and instruction imposed upon young children is a condition which lies at the root of school hygiene.

There was a useful discussion on the teaching of geography at a joint meeting with the geographical section, but as a short account of this has already appeared in the report of the proceedings of that section, no further reference need be made to it here.

R. A. G.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. T. H. Havelock, Smith's prizeman and Isaac Newton student in astronomy and astronomical physics, 1902, was on November 2 elected to a fellowship at St. John's College.

Mr. J. M. Dodds, Peterhouse, has been appointed chairman of the examiners for the mathematical tripos.

The university contribution from the incomes of the colleges has been fixed for the year at $12\frac{1}{3}$ per cent. This will yield the sum of 28,076*l.* to the common university fund.

The council of the Senate has proposed that a syndicate be appointed to consider whether it is expedient to make any changes in the present system of studies, teaching, and examinations of the university. It has been urged, it is said by His Grace the Chancellor, that some changes are desirable, especially as regards modifications of the requirements concerning the classical languages, and enlargement of the range of modern subjects. The reorganisation of secondary education throughout the country, and recent developments in other universities, have made the inquiry more than ever desirable.

IN small schools with limited accommodation, where instruction is given in both chemistry and physics, it is almost impossible to have separate laboratories for practical instruction in these subjects. Messrs. F. E. Becker and Co., of Hatton Wall, London, are manufacturing a combined bench for chemical and physical experimental work which succeeds in overcoming this difficulty. When the benches are required for a chemistry class there are shelves for bottles of reagents on much the same plan as in ordinary chemical laboratories, but when the benches are to be used for practical physics, the shelves and reagents can be safely lowered bodily until they are below the surface of the bench. The lowering is effected by weights, heavier than the shelves and their contents, attached to sash cords running over pulleys. This plan is a decided improvement upon the attempt to make the reagent shelves of such a pattern that they may be lifted when the benches are required by students of physics.

A COURSE of eight lectures on the fossil reptiles of South Africa was commenced by Prof. H. G. Seeley, F.R.S., at King's College, Strand, on Tuesday, and will be delivered on alternate Tuesdays until February 23, 1904. The lectures are addressed to advanced students of the University of London and others interested in zoology and palæontology, and to persons specially interested in the South African colonies. There is no fee for the course; cards of admission may be obtained on application to the academic registrar of the university. Other courses of special lectures in advanced zoology have been arranged, including the following, to be delivered next year:—Prof. E. A. Minchin, "Sporozoa"; Dr. P. Chalmers Mitchell, "The Structure and Classification of Birds"; Dr. C. W. Andrews, "The Fossil Vertebrates of Egypt and their Relations with those of other Regions"; Prof. H. G. Seeley, F.R.S., "The Forms of the Skull in the Extinct Reptilia" and "The Limbs and Arches which Support them in some Extinct Vertebrata."

THE Chester Society of Natural Science, Literature and Art, which now numbers more than a thousand members, held its thirty-second annual conversazione on October 22, when the Kingsley memorial prizes for nature-study offered for competition by the Chester Society were presented by the Duchess of Westminster. These prizes, of the value of a guinea each, are offered to boys and girls residing in Cheshire and North Wales, and this year the subjects selected for the competition were:—the life-history and habits of the common house sparrow; the collection of dried and mounted specimens of British grasses; the physical geography and natural features of the district in which the competitor resides; and a descriptive list of insects which are injurious to plants in the district in which the competitor resides. So far as practicable, the list of insects was to be accompanied by actual specimens of the insects tabulated. This plan, which the Chester Society of Natural Science has found successful in developing an interest in nature-study in the schools of Cheshire and North Wales, might with advantage be adopted by field clubs and natural history societies in other parts of the country.

AT Liverpool on October 31 Lord Londonderry opened a new wing erected in connection with Edge Hill Training College at a cost of 11,800*l.* Lord Londonderry, in the course of his address, said the universities were undertaking new and remarkable phases of work. Liverpool, Manchester, and Birmingham, which twenty years ago could not stand alone, were now eager for independence, and were anxious to discharge in their own way the duties of higher education. To be successful we must have an education system second to none. We had a considerable amount of leeway to make up, because we had not at the present time the advantages which were enjoyed by other countries in regard to this question. He wished it were possible that they could at once take the steps necessary to compete successfully and in friendly rivalry with other countries, but he trusted the day was not far distant when that might be done. It was the work of colleges which might induce the country at some future date to devote a sum of money annually to assist picked men and women engaged in research studies thoroughly to complete their education. He must not, however, be understood to be making any pledge that he had any such prospect in view.

THE classes at the Northern Polytechnic have for the last few years been greatly crowded, especially in physics, chemistry, and some of the trade subjects. To provide the necessary accommodation a large new wing has been constructed, to which the physics department has been transferred. This is now provided, amongst others, with three large laboratories, two of them 50 feet by 30 feet, and a lecture room that will seat about 100. On the top floor, in addition to the accommodation for chemistry already existing, are now added a large elementary laboratory, a laboratory specially fitted for honours students and research work, as well as a balance, a lecture room, and a fire-proof room. The new wing also contains a drawing office 50 feet by 30 feet, and four trade shops, for plasterers, masons, bricklayers, and painters respectively. The cost of this wing, with its equipment, has amounted to about 16,000*l.* The chemical laboratories, drawing office, and several trade shops are lighted by "inverted arcs," that is, by the light reflected from the ceiling only, upon which the arc lamps are caused to shine. The result is a light so diffused as to be almost shadowless, and therefore an exceedingly pleasant light for mechanical drawing and such things as masonry, in which there may be a lot of undercut work, which an ordinary light would make difficult. This wing was formally opened on Wednesday, October 28, by Lord Londonderry. Sir Arthur Rücker, Mr. Sydney Webb, and Sir Joseph Savory were among the speakers.

THE second article by a special *Times* correspondent on the work of the Mosely Educational Commission, published in the issue for October 28, contains several useful and suggestive expressions of opinion as to certain of the causes for the greater educational enthusiasm in the United States as compared with that in this country. The article states that "in England every penny spent on education is too often grudged; in America there is no public expenditure that seems to meet with more universal approval." Perhaps, the article continues, it is this belief in education for its own sake that has saved America from the whole system of examinations, scholarships, and prizes, under which English education groans. In our elementary schools the examination fiend has been partly exorcised, with the result that at this moment elementary education in England is in a healthier and freer condition than that of the secondary schools and universities. There, where education ought above all to be free to develop itself in the best methods and from the highest motives, the case is notoriously the reverse. From the time he enters a preparatory school until he leaves the university, an English boy imbibes the idea that the principal object of study is to pass examinations. Teachers must repress individuality of treatment, and with one eye on the nearest impending examination must think less of educating their pupils than of cramming them. Secondary schoolmasters dare not travel outside the require-

ments of university scholarship examinations, while preparatory schoolmasters must adapt their teaching to the competition for entrance scholarships at the secondary schools. Our whole system of higher education has got into a vicious groove of incessant competition. If the Commission succeeds in its mission, which is to stir up Englishmen to greater educational endeavour, it will have performed a great national service.

LECTURING on "The Work and Aims of the London University" on Monday evening at the London Institution, Sir Arthur Rücker remarked that a modern university had to concern itself with teaching, with research, and with technology. The London University was bound by its statutes to organise, improve, and extend higher education within a radius of thirty miles of the university buildings, but it started on this great task very sparsely equipped with funds. The Government gave a dignified centre in the Imperial Institute buildings and 8000*l*. a year, which was calculated to supply the actual needs of the university for the central staff and for carrying on the examinations, leaving the sum of 1500*l*. yearly with which to improve, organise, and extend higher education in London and thirty miles around. However, the London County Council put aside an annual grant of 10,000*l*. for the university, and that had enabled it to start from the first as a teaching university. It was essential, in carrying on the work, that the efforts of the university should at particular times be concentrated on particular objects, and at present three schemes had been proposed. The first of these was the incorporation of University College, which has offered to place its whole property at the disposal of the university and under its control. In order to carry out this scheme 200,000*l*. was needed to make the college ready for incorporation. The Drapers' Company had given 30,000*l*. for this object, and altogether about 100,000*l*. had been raised. But the scheme was delayed for the want of another like amount. The second scheme was connected with the great medical schools of London. They were at present hampered by the necessity of providing education in subjects such as physics and chemistry, which could be equally well taught at a distance from a hospital, and they were anxious that the university should undertake the whole of that work. This proposal would coordinate teaching in London, and a beginning could be made if 100,000*l*. were provided. The third scheme was that of a new college of technology proposed by Lord Rosebery. Large sums had been promised by private donors for this purpose, and the County Council had promised 20,000*l*. a year as an endowment if certain reasonable conditions were fulfilled. It was understood that about 100,000*l*. more was needed to carry out this plan also. Upon the carrying out of these schemes depended, among other things, whether the university was to be in reality a great teaching body or not.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, October 23.—Dr. R. T. Glazebrook, F.R.S., president, in the chair.—The bending of magnetometer deflection-bars, by Dr. C. **Chree**. A theoretical paper contributed to the Society by the present author in May, 1901, proved, amongst other results, that the bending of the deflection-bar of an ordinary magnetometer, under the combined weight of the bar and its load, must increase the distance between the deflecting and deflected magnets, during a determination of horizontal force, to an extent which is not negligible. This conclusion has been borne out by direct observations made at the National Physical Laboratory on a number of magnetometer-bars, including specimens from the leading makers. The mean results thus obtained are recorded in the present paper. In many magnetometers the increase in distance due to the bending is roughly proportional to the distance itself. In the case of bars by the Cambridge Instrument Company, the bending increased the distance by almost exactly 1 part in 10,000 at all distances. It is hoped that the method employed will prove useful to magnetic observers who have not ready access to a physical laboratory.—On the magnetism of basalt and the magnetic behaviour of basaltic bars when heated in air, by Dr. G. E. **Allan**. Bars cut from basalt obtained from Rowley Regis and from Linz, Germany, were tested by means of a magnetometric method to determine their magnetic properties at temperatures from 15° to 800° C. Hysteresis curves are given, and the temperature-permeability curves show that whilst the English basalt has, in general, a maximum permeability near 500° C., followed by a minimum about 550° C., the temperature of maximum permeability in the case of the German basalt lay in the neighbourhood of 50° C., there being a subsequent gradual loss of strength with rise of temperature. Sections of heated and unheated rocks are given, showing evidence of chemical change in some of the rock constituents, and a table of values of susceptibility of the specimens is appended.

Royal Microscopical Society, October 21.—Dr. Hy. Woodward, F.R.S., president, in the chair.—Mr. J. W. **Gordon** exhibited some photomicrographs of *Pleurosigma angulatum*, taken with a 1/14th inch oil immersion objective, the magnified image being received on an oscillation screen; the image so obtained was further magnified 150 times by a second microscope placed above the first, the arrangement being similar to that exhibited and described by Mr. Gordon when he read his paper on the Helmholtz theory of the microscope. The photograph was then enlarged by the usual process. The source of illumination was a pin-hole lighted by a Welsbach burner, but Mr. Gordon thought it would be better to use a lime-light for the purpose, as the threads of the mantle produced a somewhat striped effect, which rather impaired the appearance of the photograph.—Mr. C. D. **Soar** exhibited on the screen by means of the epidiascope a large number of drawings of British water mites, one or more species of each genus being included in the series. He gave a brief explanation of the special characters of each species shown.—A paper by Mr. F. W. **Millett**, being part xv. of his report on the Foraminifera of the Malay Archipelago, was taken as read.

Challenger Society, October 28.—Sir John Murray, F.R.S., in the chair.—Dr. R. N. **Wolfenden** read a paper on the distribution of the Copepoda as illustrated by his cruises from Valentia to the Færöe Banks and in the "cold area" of the Færöe Channel. Two species proved to be purely epiplanktonic, both in the warm and cold areas, twelve were eurythermic and eurybathic, ranging from the surface to 700 fathoms in both areas. Forty-seven out of sixty-four in the warm Atlantic, and twenty-three out of forty-seven species in the cold area, were mesoplanktonic, and not met with in the adult condition at less than 200 fathoms, although some few were epiplanktonic when young. No less than thirteen species were captured at 1000 fathoms. There is evidence that certain forms are confined to the bottom, and form part of a true hypoplankton (in the sense in which that word was originally introduced); mesoplanktonic forms are found among these latter.—Dr. E. J. **Allen** contributed notes on the changes observed in the water temperatures and plankton southwest of the Eddystone.—Mr. L. A. **Borradaile** exhibited and made remarks on symbiotic crabs from the Maldive Islands.—Mr. **Bidder** showed and explained a new meter for bottom currents.

PARIS

Academy of Sciences, October 27.—M. Albert Gaudry in the chair.—On the scintillating phosphorescence presented by certain substances under the action of the radium rays, by M. Henri **Becquerel**. By working with the radium emanation in a strong magnetic field it was clearly proved that it is the α rays which cause the scintillation, this result being in agreement with the suggestion of Sir W. Crookes: the phosphorescence excited by the β rays, when it is appreciable, masks the effect of the α rays. The double sulphate of uranium and potassium is rendered phosphorescent by the β rays, the platinocyanide of barium by both α and β rays, whilst hexagonal blende and diamond are especially affected by the α rays, the phenomenon being very brilliant with the diamond. The facts observed are all in accordance with the hypothesis that the scintillation is due to cleavages irregularly provoked on the crystalline

screen by the prolonged action of the α rays.—Observation of the eclipse of the sun of September 20, made at the island of Réunion, by MM. Edmond **Bordage** and A **Garsault**.—Observations of Mars made with the large telescope of the Observatory of Meudon, by M. G. **Millochau**. The appearance of the markings on the planet when viewed through the large instrument differs in some respects from the previous observations made with smaller telescopes. Four drawings accompany the paper, showing the appearance on different dates.—On the groups of transformations of linear equations of finite differences, by M. Alf. **Guldberg**.—On the practical solution of equations, by M. **Rabut**.—The experimental determination of the momentary pressure resulting from shock, by M. **Ringelmann**. The results obtained can be expressed by the formula $C = kPv$, in which C is the momentary pressure, P the weight of the falling body, v its velocity, and k an experimental coefficient, 13·55.—On a capillarimeter, by MM. E. **Tassilly** and A. **Chamberland**. The instrument consists of a biconcave cylindrical lens, on the plane edges of which two plane parallel plates are clamped, the difference in the heights of the meniscus on either side being measured.—The change of electrical resistance of selenium under the influence of certain substances, by M. A.-B. **Griffiths**.—On the fusibility of mixtures of sulphur and bismuth, by M. H. **Pélabon**. The fusibility curve is represented by three straight lines, with two points of inflection, one at 435° C. and the other at 685° C., the latter corresponding to the sulphide BiS.—The action of boric acid upon iodides; its use in the separation of iodine from iodides in the presence of bromides and chlorides, by MM. H. **Baubigny** and P. **Rivals**. Iodine can be separated from a mixture of haloid salts by distilling with boric acid and manganese peroxide in a current of air.—On the composition of the prehistoric bronzes of Charente, by M. **Chesneau**.—The calculation of the heat of combustion of organic acids, their anhydrides and esters, by M. P. **Lemoult**. By assuming certain thermal values for the (CO.OH), (C=C), (CO.O.CO), and (CO.O.C) groups, a general formula is given for the heat of combustion of the above named substances. On 450 cases examined, in 12 per cent. the approximation is within 1 per cent., in·20 per cent. between 1 and 0·5 per cent., and in 68 per cent. within 0·5 per cent. of the experimental values.—Researches on isoglucosamine, by M. L. **Maquenne**. Isoglucosamine is reduced by sodium amalgam to two stereoisomeric bases, one being *d*-glucamine, the other *d*-mannamine. Isoglucosamine thus furnishes a new means of passing from the mannite to the sorbite series.—The action of chlorine on barium acetate, by M. Albert **Colson**. A chloroacetate is formed of the composition $[BaCl.(C_2H_3O_2)+H.(C_2H_3O_2)]$.—Solid azo-colouring matters derived from α-amino-anthraquinone, by M. Charles **Lauth**.—Study of some ancient samples of bread. An examination of bread from Pompeii, Aosta, Egyptian tombs, and the lake dwellings of Neuchatel, by M. L. **Lindet**.—The tectonic structure of the island of Eubea, by M. **Deprat**.—Study of the muscular contractions and of the reflexes in *Stichopus regalis*, by M. Victor **Henri**.—On the stimulation of nerves and muscles by discharges from condensers, by M. J. **Cluzet**.—The seat of epileptiform convulsions, by M. Nino **Samaja**.—A new dental and surgical drill, by MM. J. **Bercut** and A. **Donat**.—On the curve of output of a subterranean spring, by M. Edmond **Maillet**.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 5.

CHEMICAL SOCIETY, at 8.—Conductivity of Substances Dissolved in Certain Liquefied Gases. Preliminary Notice: B. D. Steele and D. McIntosh.—The Reduction of Hydrazoic Acid: W. T. Cooke.—The Behaviour of Metallic Oxides towards Fused Boric Anhydride: C. H. Burgess and A. Holt, Jun.—Some Reactions of Vanadium Tetrachloride: B. D. Steele.—Studies on Comparative Cryoscopy. Part I.: The Fatty Acids and their Derivatives in Phenol Solution: P. W. Robertson.—The Vapour Pressures of Sulphuric Acid Solutions. Preliminary Note: B. C. Burt.—The Viscosity of Liquid Mixtures. Preliminary Note: A. E. Dunstan and W. H. C. Jemmett.—Additive Compounds of s-Trinitrobenzene and Alkylated Arylamines: H. Hibbert and J. J. Sudborough.—A Contribution to the Study of the Reactions of Hydrogen Peroxide: J. McLachlan.—The Constitution of Certain Silicates: C. Simmonds.—Constitution of Ethyl Cyanacetate. Condensation of Ethyl Cyanacetate with its Enolic Form: P. Remfry and J. F. Thorpe.—Interaction between Chloric and Hydriodic Acids: J. McCrae.—3:5:-Dichloro-1:1:2-Trimethyldihydrobenzene. A Correction: A. W. Crossley.—The Estimation of Hydroxylamine: H. O. Jones and F. W. Carpenter.—A Study of the Isomerism and Optical Activity of Quinquevalent Nitrogen Compounds: H. O. Jones.—The Action of Water and Dilute Caustic Soda Solutions on Crystalline and Amorphous Arsenic: W. T. Cooke.—The Union of Carbon Monoxide and Oxygen, and the Drying of Gases by Cooling: A. F. Girvan.

RONTGEN SOCIETY, at 8.30.—President's Address.

LINNEAN SOCIETY, at 8.—On the Structure of the Leaves of the Bracken, *Pteris aquilina*, in relation to environment: L. A. Boodle.—On the Life-history of a New Monophlebus from India, with a Note on that of a Vedalia predaceous upon it; with Remarks on the Monophlebinæ of the Indian Region: E. P. Stebbing.

FRIDAY, NOVEMBER 6.

GEOLOGISTS' ASSOCIATION, at 8.—Conversazione at University College.

TUESDAY, NOVEMBER 10.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—North Polar Exploration, 1898–1902: Commander R. E. Peary, U.S.N.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Tensile Tests of Mild Steel, and the Relation of Elongation to the Size of the Test-bar: Prof. W. C. Unwin, F.R.S.

ANTHROPOLOGICAL INSTITUTE, at 8.15.—Exhibition of Pictures Painted by Colour-blind Persons: Dr. F. W. Edridge-Green.—The Survival of Primitive Implements in the Færöes and Iceland: N. Annandale.—Anthropological Notes on Kikuyu and Kamba: H. R. Tate.

THURSDAY, NOVEMBER 12.

MATHEMATICAL SOCIETY, at 5.30.—Annual General Meeting.—On Sequences of Sets of Intervals containing a Given Set of Points: W. H. Young.—On Spherical Curves: H. Hilton.—On the Weddle Quartic Surface: Dr. H. F. Baker.—A Formal Generalisation of Maclaurin's Theorem: Rev. F. H. Jackson.—Diffraction: W. H. Jackson.—A General Theorem concerning Absolutely Convergent Series: G. H. Hardy.—Note on Borgnet's Method of Dividing an Angle in an Arbitrary Ratio: Prof. J. D. Everett.—On an Expression of the Electromagnetic Field by Means of Two Scalar Potential Functions: E. T. Whittaker.—The Propagation of Wave-motion in an Isotropic Elastic Solid Medium: Prof. A. E. H. Love.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Inaugural Address by the President, Mr. Robert Kaye Gray.

FRIDAY, NOVEMBER 13.

ROYAL ASTRONOMICAL SOCIETY, at 5.

PHYSICAL SOCIETY, at 8.—(1) Means for Electrifying the Atmosphere on a Large Scale: (2) an Arrangement for driving Mercury Pumps: Sir Oliver J. Lodge.

THURSDAY, NOVEMBER 12, 1903.

THE SCIENTIFIC WORK OF THE IMPERIAL INSTITUTE.

Imperial Institute: Technical Reports and Scientific Papers. Edited by Wyndham R. Dunstan, M.A., F.R.S., with a preface by the late Sir Frederick Abel, Bart., G.C.V.O., K.C.B., F.R.S. Pp. xlvii + 613. (London: Imperial Institute, 1903.)

OF the several purposes which the Imperial Institute was designed to serve, there is probably none which has been less regarded by the general public than that of scientific and technical research. Such work, however, was definitely one of the objects the advisory committee had in view when considering the proposed building some seventeen years ago; for, as the late Sir Frederick Abel has recorded, this committee was of opinion that the Institute would " afford accommodation for comparing and examining samples by the resources of modern science." In the furtherance of this design there has been gradually evolved an experimental branch, which eventually became known as the " Scientific and Technical Department " of the Institute. At the present time the staff includes ten assistants under the direction of Prof. Dunstan, and the chemical laboratories entirely occupy the upper floor of one wing of the Institute buildings, whilst the help of outside specialists, manufacturers, and commercial experts is invoked as occasion requires.

How this department struggled into existence is described by Sir Frederick in the preface to the volume under notice. It is rather pathetic reading sometimes. There was a difficulty in making any start at all, and to satisfy the " eternal want of pence " afterwards was a harder task still. Hat in hand the committee had to go, begging for money here and for professional help there, first getting, for example, " rupees to the value of 64*l*. 8*s*. 2*d*." from the Indian Government; then a grant of 300*l*. from the Commissioners of the 1851 Exhibition; next, " small gifts of money, and of some indispensable instruments " from such well-wishers as Sir Lowthian Bell and Dr. Mond; then a donation of 1000*l*. from the Goldsmiths' Company; and so on. How often, in those days, must the organisers have sighed for a sympathetic millionaire! Still—*solvitur laborando*—the thing was eventually done, and in 1896 the department, now on something like a stable footing, was taken in charge by Prof. Dunstan as director.

For the subsequent maintenance of the laboratories thanks are largely due to the Commissioners of the Exhibition of 1851. Acting with a wise liberality, the Commissioners in 1896 made the department a grant of 1000*l*. *per annum* for a term of years, and to this was added a second grant of a like amount two years later. In view of the work accomplished, this contribution of 2000*l*. *per annum* has been continued, and is still enjoyed by the department.

One question, however, may naturally be asked in connection with this matter. Should not the Government, now that it has taken the Institute under its wing, be induced to place the scientific department on a permanent footing—or at least to become wholly responsible for its support? There appears to be no reason why the Commissioners of the 1851 Exhibition should still assist in carrying on the work.

What has been accomplished by the scientific staff since 1896 is mainly set forth in the present volume. Part i. comprises a large number of technical reports upon various industrial products sent from India and the Colonies, with the view of ascertaining their commercial value and whether there was likely to be any market for them in this country or elsewhere. Minerals of several kinds (including coal, clay, iron-ores, and mica), fibres, oils, rubber, gums and resins, tanning materials, medicinal and food plants, timbers, and miscellaneous articles such as wines, aloes, and capsicums, have been examined and reported upon more or less exhaustively, with the practical result that in some cases a commercial demand has arisen for the article in question, and in others arrangements have been made for a regular supply of the substance, or, it may be, for its improved production and utilisation. Especially noteworthy would seem to be the recognition of *Caesalpinia digyna* as a tanning agent, and of *Podophyllum emodi* and *Hyoscyamus muticus* as sources of the drugs podophyllin and hyoscyamine respectively.

An interesting paper on the coal resources of India is included as an appendix to Part i. To those of us " who only England know," it may come as a surprise to learn that the coal output of the Indian collieries in 1900 exceeded 6,000,000 tons, or about 1/35th of that of the United Kingdom. In quality the coal is generally inferior by about 20 per cent. to that of this country, but on account of its cheapness it is largely used by steamships plying in Indian waters, and the output has increased six-fold since 1880. The supply is considered to be practically inexhaustible. Those amongst us whose geology is local rather than cosmopolitan will learn with interest that these immense Indian deposits are all of much later date than our own Coal-measures, for they occur in the Permian, Triassic, Jurassic, and even Cretaceous and Tertiary formations.

In Part ii. are collected some thirty-five papers of a more purely scientific character. These embody the results of special chemical researches upon various plant-constituents by Prof. Dunstan and his coadjutors, and of investigations into a number of colouring-matters, chiefly by Profs. Hummel and Perkin. Readers of the Chemical Society's publications will be familiar with most of these researches, all of which are interesting, whilst some are of particular importance. The investigations upon the constituents of Indian and American podophyllum, on the aconite alkaloids, and on cyanogenesis in plants may be specially indicated as good examples of the work which has been carried out. In some cases—as, for instance, in the paper on the action of alkyl haloids on aldoximes and ketoximes—it is not quite clear how the chemical question involved was connected with the special work of the Institute, but no doubt such general points would often arise during the progress of researches upon specimens forwarded for examination. On the whole, these " scientific papers " strike

one as being admirable descriptions of useful work, well conceived and ably executed.

As a separate establishment the Imperial Institute has ceased to exist, and is now a department of the Board of Trade. In its time it has played many parts. It has exhibited nuggets to us, sold us cakes and ale, discoursed sweet music to our ears, and charmed our eyes with its fairy-lamps and coloured fires. These things have vanished, as have also many of the splendid, but rather nebulous, generalities which we used to hear concerning the Institute's prospects and probable influence as a factor in Imperial affairs. But at least the definite work of the scientific staff remains, and, presumably, such services as those now rendered will be more and more brought into requisition as time goes on. It may well happen that Prof. Dunstan's laboratory will—to paraphrase a remark of Huxley's—become the forecourt of the temple of success for some at least of the original aims of the Institute, whatever may be the fate of the remainder.

C. SIMMONDS.

BABYLONIAN DEMONOLOGY.

The Devils and Evil Spirits of Babylonia. Vol. i. By R. C. Thompson, M.A. Pp. lxv+212; with 2 plates. (London: Luzac and Co.)

THE present volume is the first of two which Mr. Thompson intends to devote to a study of the evil spirits and devils of Babylonia, and it will, we believe, be welcomed by readers of many classes. We have been long familiar with the generalisations which writers are fond of making upon this fascinating subject, but so far as we know, no one has before attempted to give a systematic account of Chaldean demonology, and to add at the same time the reasons for the faith which is in him. Those who are interested in cuneiform decipherment will remember that some few years ago the Trustees of the British Museum began to publish a series of classified Assyrian and Babylonian texts, which they issued in parts, each containing 50 plates of text. The earliest parts contained all the material for the syllabary and grammar, then followed lists of words, and afterwards Mr. L. W. King's edition of the Creation tablets. In the present year were published the sixteenth and seventeenth parts of the series, which supplied copies of all the tablets relating to "evil spirits," "fever-sickness," and "headache," carefully made by Mr. R. C. Thompson, and these are the sources of the materials which have been translated in the present volume.

Mr. Thompson gives transliterations of his cuneiform texts on the left hand pages, and English translations on the right; this is an open and honest way of working, and we hope that English Assyriologists in general will follow his example. Nowadays the student demands facts, and the text is the greatest fact of all; no linguistic study can flourish upon bad foundations, and in our opinion the work of the man who hides his texts, or only makes them partially available for students, should be viewed with suspicion. Even a bad text is better than none, for at least workers in England, France, and Germany can correct it sooner or later. In the present case the British Museum publishes the texts, and Messrs. Luzac the translations, and as each portion of the work is done by the same man we are able to ascertain our position from a scholarly point of view to a nicety.

The publication of evil spirit texts, like so much else, was begun by the late Sir H. Rawlinson, K.C.B., and attempts were made to translate his copies first by Lenormant and secondly by Prof. Sayce. Sir H. Rawlinson, however, only published selections from the great mass of cuneiform literature in the British Museum, and it follows, as a matter of course, that even where they could translate the texts, the conclusions of Lenormant and Prof. Sayce were based on incomplete and insufficient evidence. The subject of Chaldean demonology is at the best a difficult one, and we have no hesitation in saying that the earlier works on it rather hindered than helped the understanding of the matter. Now that the tablets are joined up, and their right sequence found, it becomes clear that the Assyrian scribes were not so stupid as some have thought, and that there really was method in their madness.

It is to Mr. Thompson's credit that he has found out what the Assyrian method was in respect of the evil spirit tablets, and having found this his translations possess unusual value. He will hardly, we think, claim to have settled all the difficulties which he has encountered, but there is little doubt that his present work will form the standard one on the subject for many years to come. In the course of his study we find that he had destroyed a few ideals, and more than one favourite and popular theory. It was fashionable to assert a few years ago that the British Museum contained a tablet which bore on it an allusion to the Garden of Eden, but now that the fragment referred to has been put in its right order, we see that the text on it has nothing whatever to do with the Garden of Eden, and that the tree which was supposed to be nothing more or less than the Tree of Life is the *kishkanu* plant, which grew in Eridu, and was believed merely to possess magical properties. Mr. Thompson has taken great pains to thresh this matter out, and we think that he has proved his points very thoroughly. We can only hope that this exposure will deter that class of Assyriologist which seeks for reputation and popularity by the "finding" of "Biblical parallels" from continuing its charlatanic practices. More harm has been done to Assyriology by such things than by all the mistakes which its followers, from Rawlinson down to Thompson, have made; for even the results which are certain have been discredited by many first-rate Semitic scholars who were unable to read cuneiform.

Another important result of Mr. Thompson's work is the proof that, *au fond*, the demonology of the Semitic peoples of Mesopotamia who used the cuneiform system of writing is of Sumerian origin, and there is good reason to suspect that the greater part of Babylonian psychology and eschatology were borrowed directly from their non-Semitic predecessors in the country. This remark applies also to many of the beliefs which the Hebrews took over from the Babylonians their kinsmen. Want of space will not permit the mention

of many minor points of interest in the volume before us, but we hope to refer to the subject again when the second portion of Mr. Thompson's work appears. Meanwhile, the book may be commended to all students of folk-lore, as well as to the Semitic philologist and anthropologist.

LINE GEOMETRY.

A Treatise on the Line Complex. By C. M. Jessop. Pp. xv+364. (Cambridge: University Press, 1903.) Price 10s. net.

THE systematic study of what is now called line geometry was begun by Plücker in his "Neue Geometrie des Raumes." There was, it is true, a fairly complete theory of the linear complex due to Chasles and others before the publication of Plücker's work, and the geometry of systems of lines (congruences) has in some respects not progressed very much since the date of Kümmer's celebrated memoir, but it was only after the idea of line coordinates had been introduced that the essential qualities of the new geometry were recognised.

In his treatise on the line complex, Mr. Jessop has aimed at presenting the extensive investigations of German and Italian geometers in a form easily accessible to the English student of mathematics. It has been found necessary to write an introductory chapter on the elementary methods of synthetic geometry that are used in the book; then the next four chapters contain the theory of line coordinates, in the general form introduced by Klein, and the linear complex. A great portion of these chapters will be familiar to anyone who has studied the theory of forces in three dimensions with attention; the only omission that occurs to us is a number of easy exercises on the use of line coordinates, particularly in the ordinary Cartesian form, but this defect is partly remedied by an excellent collection of examples at the end of the book.

The theory of the quadratic complex is naturally the most important part of the book—the linear complex is too well known, and the higher complexes too difficult to deal with, to illustrate the methods of the subject. The author has devoted six ample chapters (vi.–xi.) to this theory. Chapter vi. deals mainly with the singular surface, which is remarkable in all complexes as being both the locus of singular points and the envelope of singular planes. Two proofs of the identity of this locus and envelope are given, one depending on von Staudt's theorem concerning a tetrahedron, and the other on infinitesimal properties. The first is particularly interesting although peculiar to the quadratic complex, because a tetrahedron being the simplest form of the singular surface, von Staudt's theorem is a particular case of a property of Kümmer's quartic from which the result follows; the other proof can be extended readily to any complex (chapter xvii.). The discussion of Kümmer's quartic is the author's own, and will be very welcome to the beginner as being both elementary and direct.

It is curious that an infinite number of quadratic complexes have the same singular surface, the theory being similar to that of confocal quadrics. Such cosingular complexes are discussed in chapter viii., and by developing the idea of corresponding lines in cosingular complexes Mr. Jessop has obtained some very interesting and novel proofs. Another chapter deals with the beautiful classification of quadratic complexes, and contains an exposition of Darboux's proof of the fundamental theorem of Weierstrass on the equivalence of quadratic forms.

In chapter vii. an account of some special complexes is given, the greater part of the space being devoted to the tetrahedral complex; this complex was studied long before the introduction of line coordinates, and lends itself readily to synthetic treatment.

In another part of the book it is shown that a tetrahedral complex can always be found which contains the complete intersection of a quadratic complex and a linear complex. Substantially this important result is due to Kümmer, but the first complete account of it we owe to Caporali.

Only two chapters on congruences appear in the work; this part of the subject is difficult, because the analytical methods are clumsy when applied to such congruences as are not complete intersections of complexes, and the purely synthetic methods of Sturm and others are extremely tedious. Mr. Jessop follows Kümmer on the general principles, and only gives a detailed account of the simplest congruence, namely, that of the second order and the second class.

The latter portion of the book does not strike us as being so attractively arranged as the earlier parts, but the final chapter on the connection of line geometry and differential equations is valuable as an introduction to Lie's theories.

There is no doubt that the book will be a boon to a student of the subject, and that anyone with a taste for geometry will find much that is interesting and something that is new in it. J. H. G.

OUR BOOK SHELF.

Geological Rambles in East Yorkshire. By Thomas Sheppard, F.G.S. Pp. xi+235; 53 illustrations and geological map. (London: A. Brown and Sons, 1903.)

THIS is a pleasantly written and attractive guide to the geology of east Yorkshire, the work of a sturdy local geologist who shows himself to be master of his subject and of the literature past and present. Under his enthusiastic leadership we are taken from Hull to the out-of-the-world promontory of Spurn Head, where we learn many lessons about recent geological changes. Thence we are conducted northwards to Withernsea and Hornsea, examining some of the finest sections in the Boulder-clay of Yorkshire; successive beds of drift with transported mollusca and Scandinavian rocks, deposits with local detritus, and others with rocks from the Cheviots and elsewhere. We see also lacustrine deposits and peat beds, remains of old lakes, of which Hornsea Mere alone appears to survive. Then we are taken on to Bridlington, noted for its shelly "Crag," really a part of the basement Glacial drift, which is now hidden behind a strong sea-wall. The buried cliff of Sewerby, with its basement clay and older mammaliferous deposit yielding *Elephas antiquus*, hippopotamus, rhinoceros, &c., claims attention. From this we pass on to the fine

Chalk cliffs of Flamborough Head, beginning near Sewerby with beds which are rich in sponges and yield also Marsupites, and we continue along the headland to lower divisions of Chalk at Selwick, Thornwick and Bempton, and finally to the base with its Red Chalk at Speeton. Here, amid a region of landslips, we notice one slip on the part of the author (p. 61), where he refers to the Red Chalk of Cromer, meaning, of course, Hunstanton. The Speeton Clay, as unravelled by Mr. G. W. Lamplugh, is duly described, from the Gault through the Lower Cretaceous which constitutes the Speeton Clay proper, to the Kimeridge Clay. From this tract we are taken to the Corallian rocks of Filey Brigg, and on to Gristhorpe and Scarborough, where the work of Mr. W. H. Hudleston and Mr. Fox-Strangways, as well as that of earlier geologists, is duly mentioned.

Thus all the Jurassic divisions are in turn described as we proceed along the coast, as the author takes us to the Lias of Robin Hood's Bay, Whitby and Redcar. He then brings us back to the Humber, discourses on the warp, which is material not carried down by the rivers, but derived from the waste of the Boulder-clay cliffs and brought in by the tide. From Hull again to Hessle we see more of Glacial drifts; we are taken over the Oolites of Brough and South Cave, and across the Yorkshire Wolds, the charms of which are well described, and thence we come back to Holderness.

The work is admirably illustrated with photographic views, many of them taken by Mr. Godfrey Bingley, and from its clear and accurate descriptions it is well calculated to rouse up and foster an interest in geology.

Les Produits coloniaux d'Origine animale (Bibliothèque Coloniale). By H. J. de Cordemoy. Pp. viii+396; illustrated. (Paris: Baillière et Fils, 1903.) Price 5 francs.

THE object of the series of which the volume before us forms a part is to bring before the French public in an interesting and popular style the origin of the foreign food supplies and products used in the arts and commerce, and more especially those which are yielded by their own colonies. The idea is an excellent one which might well be copied in this country, and, so far at any rate as the present volume is concerned, the Colonial Institute of Marseilles, to which the series owes its conception, is to be congratulated on the project.

The author of the present volume divides his subject into two main headings, the one including foreign food supplies and the other all colonial products of animal origin employed in French industries and arts. As regards the first section, attention is concentrated in one chapter on the manufacture of beef-essence in Madagascar and New Caledonia, while the second, and much larger one, is devoted to fish and fishing, and such special products as edible swallow-nests, bêche-de-mer, &c. The most valuable fishery appears to be that for thunny on the Tunisian coast, the concession for which is let to Count Raffo for forty years at an annual rent of 5400 francs. The most remarkable fishery at Tunis is that of octopus. Poor food one would think; but it appears that in Greece and Crete there are two annual fasts, during which the consumption, not only of meat, but of fish and the flesh of all animals "having blood is prohibited." As the octopus is not considered to come within this prohibition, it forms, in a dried condition, an important food supply during the seasons in question.

As regards the second and much larger section of the work, limitations of space render anything approaching a detailed notice an impossibility. It must suffice, therefore, to state that this section is subdivided into three groups. Under the first, which includes products used in leather and textile manufactures, as well as for dress and ornament, are classed silk, hides, furs, hair, wool, feathers, ivory, coral, sponge, tortoiseshell, mother-of-pearl, horn, &c. In the second group are ranged wax, fat, oil, gelatin, and perfumes; while the third and last group is devoted to resinous products, such as lac, and the dyes afforded by the cochineal insect and other animals.

While congratulating the author on the amount of information he has conveyed in a small space, and on the interesting manner in which this is described, we venture to think that the illustrations, some of which are too large for the pages, are hardly up to modern methods and requirements. R. L.

A Text-book of Botany. By Dr. E. Strasburger, Fritz Noll, H. Schenck, and the late A. F. W. Schimper. Second edition, revised with the fifth German edition, by W. H. Lang. Pp. ix + 671; with 686 illustrations, in part coloured. (London: Macmillan and Co., Ltd., 1903.) Price 18*s.* net.

THE new edition of the English version of the "Bonn Text-book" is based on the fifth German edition. It marks an improvement on its predecessor, and is brought well up-to-date as regards the text, whilst we also note an improvement in the figures, some of the older illustrations having been omitted or replaced by better ones. The coloured representations, however, do not strike us as very useful, and we would have willingly seen them disappear.

The principal innovation in the present volume consists in the inclusion of a bibliography, which, without pretending to be complete, cannot fail to be of use to the serious student who wishes to find his way about the literature of the science.

The popularity already enjoyed by this treatise (in spite of defects inherent in any attempt to compress a big subject into the narrow limits of a single volume) is well deserved, and Dr. Lang is to be congratulated on the excellence with which he has carried out his share in presenting the book to English students.

Bacteria in Milk and its Products. By Prof. H. W. Conn, Ph.D. Pp. vii + 306. (London: Rebman, Ltd., 1903.) Price 6*s.* net.

THIS little book gives an excellent account of the relation between milk and its products and bacteria and allied organisms. It is written in simple language, and might be read with profit by those engaged in the "milk" industries who have had little scientific training. After a few introductory pages upon the nature of bacteria, the bacterial contamination of normal milk is discussed, and plain directions are given for its reduction, milk vessels, water supply, milking, cooling, and the sanitary control of dairies being all dealt with. The various fermentations that occur in milk, milk from diseased cows, the sterilisation of milk, cream ripening, artificial starters, butter and cheese, are some of the subjects considered in later chapters, and the book concludes with directions for the bacteriological analysis of milk and for some of the simpler chemical determinations. A full bibliography is appended, but the titles are too contracted; in many instances it is difficult to recognise the publication to which reference is made.

R. T. HEWLETT.

Junior Algebra Examination Papers. By S. W. Finn. Pp. vi + 87. (London: Methuen and Co., 1903.) Price 1*s.*

THE seventy-two examination papers contained in this little book are modelled on questions set at such school examinations as the university locals. The questions are graduated, and full answers are supplied. A useful table of contents enables the teacher to discover rapidly the scope of the different test papers.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Hyksos-Hittites.

IN the *Times* of October 28 there appeared, under the signatures of Prof. J. M. Mackay, of Liverpool University, and Messrs. Percy Newberry and John Garstang, a letter on an important archæological subject, entitled "Etruscan and Hyksos—a Hittite Clue." The object of this letter appears to have been to prove a culture-connection in the second millennium, B.C., between the Etruscans in Italy, the Kheta or "Hittites" in Asia Minor and northern Syria, and the mysterious Hyksos or "Shepherd Kings" who invaded Egypt, and usurped its government between the thirteenth and eighteenth dynasties.

The subject is, of course, one of considerable interest, and the theory is a suggestive one, but readers of the *Times* would hardly guess from the tenor of this letter that the theory enunciated in it has been well known to all archæologists for the last fourteen years at least! In fact, the theory was adumbrated by several workers in the field of Oriental archæology before it was finally thrown into a concrete form and placed before scholars by Father A. C. de Cara, in the year 1889. As expounded by this learned Jesuit, the theory is simply repeated by the three writers of the letter already mentioned; hardly any original additions are made, and these are not of a character to command the adherence of students. For example, it is suggested, though not definitely said, that the well-known company of immigrants from Asia depicted on the walls of the tomb of Khnemu-hetep at Beni Hasan was a party of "Hittites." Unluckily, however, these people are Semitic in feature, and the name of their chief, Abesha, is, judging by all analogy, Semitic. Now we are quite certain that the features of the Kheta, and their names also, were non-Semitic. This Prince Abesha, the writers of the letter say, "is entitled the ruler of a foreign (mountainous) land—the Sinaitic deserts, it has been conjectured, to the south of Hebron, where Hittite and Semite had intercourse and intermarriage in the age of the Patriarchs." Here an unwarrantable assumption, and even this is not original, has been made, for there is no proof that the "children of Heth," who in the Bible are said to have lived near Hebron, are of the same race or nation as the Hittim of northern Syria, who are certainly to be identified with the Khatti of the Assyrian records and the Kheta of the Egyptian monuments, who were undoubtedly the builders of the great sanctuaries of Boghaz Köi and Eyuk, and to whom the inscriptions commonly called "Hittite" belonged.

The writers of the letter also show confusion of thought in the following matter. After stating that in the statues of Queen Nefert and Amenemhāt III. a clear Mongolian or Turanian strain is visible, and noting that "she wears on her head a horse-shoe-like attire, he a pigtail to his wig," they go on to say that the statues which the Hyksos made or usurped are Mongoloid, "Turanian on a Semitic stock, Hittite-Semite." The conclusion seems to be that these "Mongoloid" Hyksos had appeared in Egypt, and had assumed its government before the reign of Amenemhāt III., but the statues referred to are well known to belong to the reign of Amenemhāt, and were usurped by the Hyksos; therefore we have no proof whatever from the statues that the Hyksos were Mongols, and from this it follows that the "Mongoloid" Nefert and Amenemhāt III. cannot be proved to be Hyksos-Hittites. Further, the idea that the statues of Amenemhat's reign are Mongoloid at all is a pure matter of opinion, on which many archæologists would differ from the writers of the letter. The horse-shoe headdress of Nefert is an ordinary Egyptian woman's wig in the fashion of the twelfth dynasty, and Amenemhāt's pigtail is no proof that he was a Mongol; it might just as well be argued that Frederick the Great was a Mongol because he wore a pig-tail.

So much for mistakes. It is a matter for surprise that three writers who thought fit to send a communication to the *Times* on an important archæological matter should have been, as it appears, totally unaware of the long priority of another writer in the whole field of which their letter treats. X.

Telegraphic Disturbances in Spain on October 31.

ON Saturday, October 31, the telegraphic communication was interrupted almost from morning until late at night. The first sign of the perturbation was observed at 9h. 30m. in the morning (W.E.T.) in the form of continuous currents along nearly all the lines that start from Madrid. At first it was thought that some leakage from a cable in the vicinity of the Central Office was the cause of the phenomenon, but on making inquiries it was ascertained that the same occurrence was observed in Cordoba, in the line to Málaga. At the same time the cable from Vigo to Emden was rendered useless, and at Lisbon the phenomenon was observed at some moments in which the situation was normal at Madrid. The maximum intensity took place between 12h. 30m. and 15h.; at 21h. the phenomenon had nearly ceased.

During the first hours of the evening the currents were continuous for periods of twenty to thirty minutes in some of the wires, for instance, in those of Vigo; at 22h. the current in the Coruña wire was continuous during 3m.; at 1h 45m. of November 1 the current was also continuous in the Bilbao wire. At 3h. 20m. the cable from Cadiz to Tenerife in the Canary Islands remained perturbed so strongly that the clerks made the contact with the earth to avoid the discharges.

At 19h. communication between Madrid and Burdeos was re-established; information received at the Central Office stated that the cable from Senegal to Noronha was disturbed. In Spain, in some lines running approximately east and west, the phenomenon was not observed, namely, in the coast of Andalusia, from Málaga to Almeria, but in the line from Málaga to Granada, which runs roughly to the north, the perturbation was very marked, also in the more north-easterly line from Granada to Murcia. These three lines are approximately of the same length. In the centre of Old Castile, in the transversal line from Aranda to Ariza and to Valladolid, nothing abnormal was observed; meanwhile, in the general line that runs north-south, the disturbance prevented all communication. In the provinces of Cuenca and Extremadura, the lines of which run approximately east and west, the communications remained undisturbed.

The night was clouded, so that nothing could be seen of an aurora borealis, even if a display occurred.

AUGUSTO ARCIMIS.

Instituto Central Meteorológico, Madrid, November 3.

The November Leonids.

THERE appears to be little prospect of a brilliant recurrence of the November meteors on about November 15 next, though the moon will offer little impediment, being past the last quarter. The parent comet returned unobserved to perihelion in the spring of 1899, and is now far on its outward journey, beyond the orbit of Jupiter, so that any meteors appearing this year must be at a vast distance from the supposed derivative body. There is evidence, however, that minor groups circulate along the orbit, and that these are sufficiently condensed to produce pretty rich showers in certain years, as in 1879, 1888, &c. The system or stream is no doubt a continuous one, for every year at the middle of November some meteors of the swift, streaking class are seen shooting from the radiant in the "Sickle." It is obviously necessary, as a means to increase our knowledge of the shower, to watch for the display annually, and to record the time of its maximum and the observed horary number of its meteors.

The position of the radiant has been frequently determined in past years by eye-estimated meteor-tracks, and it now remains to obtain some further photographic records so that this feature may be more precisely ascertained. It is curious that the mean place of the radiant resulting from eye observations of meteors is nearly two degrees west of

the centre indicated by four photographic determinations of the radiant, the relative places being :—

	Radiant Point
From eye observations	$149^\circ.7+22^\circ.7$
From photographic trails	$151^\circ.5+22^\circ.2$.

Though there are now some hundreds of eye-estimated radiant points of this shower available for comparison, the resulting average place is not likely to be as accurate as the few positions obtained by photography. But even the centres derived from the latter method do not exhibit absolute agreement, the difference amounting to more than one degree in two of the cases.

It is hoped that the shower will be specially looked for on the mornings of November 15 and 16 if the atmosphere is favourable. W. F. DENNING.

Leaf Decay and Autumn Tints.

THE leaves of our forest trees at the period of the autumnal fall are not similar as respects the condition of vitality which they then have reached; that is to say, while some still retain their green colour and drop off, as it were, mechanically, the majority exhibit a change of coloration and are apparently dead or more or less decayed. The relation between these stages of vitality or decay and that of the particular colour (red, yellow, or brown) which the autumn leaves assume may be so far demonstrated by a critical scrutiny of certain constituents of the mineral matters (ash), especially the silica and lime, which they enclose at the very moment when this special and characteristic colour is displayed. In order to present to view this order of thought, the following tables of ash analyses are drawn up, the percentages being calculated on the red, yellow, or brown leaves with their petioles dried at 100° C., and on the ash minus charcoal :—

Leaves which become Red in Autumn.

	Percentage of ash	Constituents of the ash	
		SiO_2	CaO

Linden	8·9	22·2	35

Assuming that a heavy ratio of total ash and of silica therein is an indication that the life of the leaf is practically exhausted and its physiological energy at an end, we may, in view of the foregoing tables, consider two cases :—(1) where the percentage of silica is under 10 per cent., and (2) where the percentage of silica is 10 per cent. or more. It will be at once observed that every one of the leaves which turn red in autumn belong to the former category, while all those exhibiting yellow or brown tints and shades belong to the latter. This state of affairs would seem to hold good universally, provided only that the other conditions of the phenomena are equal. Hence a few other examples, such as the birch, the leaf of which, generally yellow, is occasionally dashed with red, or the ash-tree, the leaf of which has a small percentage of silica but a high percentage of ash, are omitted from the lists. Once upon a time I found some hazel leaves, which were almost as red as those of a wild cherry, to contain only about 9 per cent. of silica in the ash (whereas, according to De Saussure, it holds even as early as September 20, 22 per cent. silica). With regard to the exceptional instance of the yellow and never red ash-tree leaf, every plant analyst is aware how prone its tannic chromogen is to be, in certain circumstances, the precursor of a very dark brown shade, such as no other tree of our woodlands (except, perhaps, the holly) ever approaches. Eminently interesting and instructive is the contrast shown in the tables between the two maples as well as between the scarlet oak (*Quercus coccinea*), the magnificently tinted denizen of the American forest, and our own British oak (*Q. robur*), yellow and russet in autumn. It is known that the leaves of American maples, &c., cultivated in Europe do not exhibit such marked changes of colour, *i.e.* to rich deep scarlet, orange scarlet, deep rich purple, rich orange, dark crimson, &c., as they do in their own country. The causes of this difference are now pretty much made manifest. The soft, mild and yet glowing climatic conditions of the American woodlands sustain the vitality of the deciduous leaf to a degree not possible with us; we are rarely blessed with an Indian summer in the fall. The mineral matters flowing to the dying leaf flow in a quantity directly proportionate to the decay of its vitality. There is a drainage of substances (especially of silica) from the living portions of the arboreal organism to the dead and dying parts thereof. In such of our leaves as can resist the rigorous climatic severity, their vitality is so far sustained that the normal process of de-assimilation (the development of coloured pigment from tannic chromogen) is not impeded, though never so complete and splendid as in the glorious forests of New England.

Patterdale, Westmorland. P. Q. KEEGAN.

Variation of Atmospheric Absorption.

WITH regard to Prof. Langley's letter on the abnormal atmospheric absorption (p. 5) some observations of a different nature may be of interest.

Both this year and last I was photographing in Switzerland, using a Wynne meter for timing my exposures. In 1902 I found that the time required to darken the sensitive paper on a sunny day, at an elevation of 11,000 feet, was one second. This year the time, under exactly similar conditions, and using the same batch of paper, was three seconds. That the difference was not due to the paper being stale is shown by the negatives being equally good in the two cases.

The maximum sensitiveness of the paper is for blue light; yellow and orange do not affect it; it was exposed under a glass plate about 3 mm. thick. J. TALBOT.

Harrow-on-the-Hill, November 7.

Rocket Lightning.

MR. J. EWEN DAVIDSON (98 Banbury Road, Oxford) has directed my attention to his letter in NATURE, vol. xlvii. p. 582, describing auroral appearances associated with a thunderstorm witnessed by him in Queensland, of which he was reminded by the letters headed "Rocket Lightning" in your issue of October 22, p. 599. Comparison of the two accounts is interesting, but the phenomena appear to me not to have been identical. Mr. Davidson says what struck him most in the recent account was the description of a misty cloud above the low bank of thick cloud. In his own case there was a very thin misty condensation over the thunderstorm, extending to an altitude of 40° or 45°, and "the rosy light phenomenon and the streamers only shot up to the upper edge of this misty condensation." He says, "I did not mention the misty condensation in my letter to NATURE, as I did not then connect the two, but thought it was a mere coincidence, the one slightly veiling the other; but that there is a connection is now evident." "Both observers were practically looking upon the upper edge of a thunderstorm at a distance, and in both cases there was the misty appearance above it, with the comparatively slow upward moving light phenomena." J. D. EVERETT.

11 Leopold Road, Ealing, W., October 29.

Explosive Action of Lightning.

THE following particulars of the circumstances attending a lightning flash are perhaps worth recording.

A cedar tree (deodar) 50 feet high stood at a distance considerably less than its own height from a house at Englefield Green. The lady of the house was sitting watching the storm, but in such a position that she could not see the cedar, but could see a large part of an Araucaria (the common "monkey puzzle") just outside her window, and only 30 or 40 feet from the cedar. While watching this tree the lady saw, as she thought, a "rod" or "stick" of fire come crashing down through its branches—beating them down so that she distinctly saw them rebound. This was accompanied by a fearful noise as of a thousand pistol cracks, beside which, however, the lady had an impression of hearing the branches of the Araucaria beating together, and immediately afterwards a cloud as of steam rose from the lawn on which the trees stood. It was found that the cedar tree had been wrecked entirely. About 15 feet of the top was broken off, and apparently fell straight down—sticking in the ground almost vertically—close to the stump of the tree. The main portion of the trunk, to about 4 feet from the ground, was roughly split in two—falling right and left—one half being further burst into several pieces. There was the usual "smell of sulphur," but no sign of scorching on either of the trees.

A gentleman who saw the flash from a distance of about one-third of a mile noted that it was a straight (non-forked) flash from a small cloud low down. Other observers noted flashes of a similar character during the same storm.

The cedar tree was in vigorous growth, full of sap, and well above its *immediate* surroundings, but there were elms and a lime tree of greater height within fifty yards of it.

The movement and the "fire" in the branches of the Araucaria seem to me to suggest an electrostatic effect—a side splash—rather than the mere reflection of the flash which struck the cedar. Could the beating down of the branches be explained as the result of the sudden pulse in the air? What produced the cloud of "steam"? It would be interesting to have the opinion of an authority on lightning discharges with regard to these points.

Ordnance College, Woolwich, October 27.

The "Sky-coloured" Clouds.

DURING this summer I have seen only one display of the "sky-coloured" clouds, or "night-shining clouds" as the late Herr O. Jesse used to call them. It was on July 8, and was a bright display, the brightest I have seen for some years. It is rather singular they did not appear on other occasions so far as I have observed, and no mention of them has been made in your periodical. It may be that now Herr Jesse is deceased there has not been such a good and systematic watch maintained as formerly, or else, if they have been observed abroad, notices have not been copied into English papers. Whether the brilliancy of this one display was connected with the eruptions in the West Indies is a matter of conjecture. The volcanic dust continues to be very visible in the sky in producing the great corona round the sun all day.

THE GEOLOGY OF VANUA LEVU.[1]

VANUA LEVU, one of the two principal islands in the Fiji archipelago, according to Mr. Guppy's summary of previous investigations, has received less notice than Viti Levu, or even some of the smaller islands. The late Prof. Dana made a small collection of its rocks in 1840, and published some observations on its geology. It was visited in 1878 by Mr. J. Horne, of Mauritius, but no collections were made by him, by the *Challenger*, or by investigators under the direction of Prof. A. Agassiz, so that it offered a very promising field of research, which occupied Mr. Guppy for two years. The results, so far as concerns its geological and general physical features, and the petrology of its rocks, are described in the present volume, with reproduced photographs and other illustrations.

The long irregular outline of Vanua Levu contrasts strongly with the comparatively rounded one of Viti Levu. Its length is about 98 miles, with a breadth averaging 15 to 20 miles, its estimated area being about 2400 square miles, nearly equal to that of the county of Devon, while its maximum elevation is almost 3500 feet. Both this island and Viti Levu rise from a submarine plateau, in shape a broad irregular ring, broken in one place. An elevation of less than 100 fathoms would convert the whole area into one great mountainous island, pierced on the southern side by a fjord more than 200 fathoms deep. This platform Mr. Guppy considers to have been built up from the deeper ocean floor by submarine lava flows and associated deposits, and Vanua Levu as a composite island, formed, during a long period of emergence, by the union of a number of large and small islands, the products of submarine eruptions. The process probably began in the later Tertiary period, and volcanic eruptions have now ceased, but hot springs are not uncommon, though limited to regions where basic rocks occur. They are also restricted in vertical range, for they have not been found above the 300 feet contour line. Their temperature mostly ranges from 100° to 150° F., reaching 180° only in one case, the latter group precipitating siliceous sinter. Mr. Guppy thinks these springs are largely supplied by the "soakage" of the heavy rainfall in the mountains; if so, there must be rapid local rises in the underground temperature. A submergence of 300 feet would bring the sea over a considerable tract, chiefly basaltic plains, which are obviously continuous with the submarine plateau. One of 1000 feet would greatly reduce and indent the remaining axis of the island, while 800 feet more would convert it into a few scattered islets, which would represent the nuclei of the present composite Vanua Levu. This mode of building accounts for the irregularities of its physical structure, in which respect it contrasts markedly with the other large island, Viti Levu.

Proof of this great elevation is found in the occurrence of muds and tuffs with marine organisms up to at least 2000 feet above sea-level. Shelly and foraminiferal limestones, composed, as so often in tropical islands, partly of reef débris, partly of more or less broken shells of Mollusca, partly of Foraminifera, occur up to a height of 1100 feet, and they sometimes overlie palagonite tuffs and clays, also foraminiferal. Pteropod ooze, containing a large amount of palagonitic débris, is found up to about 500 feet, but volcanic muds, which are very abundant on the basaltic plains in association with the lava flows, reach the former elevation, while tuffs, sometimes agglomeratic, may be traced up beyond 2000 feet—all these containing Foraminifera. An instance of these deposits is shown in the illustration. Raised coral reefs are not very common, and appear to be limited to a vertical range of about 100 feet above sea-level, so that in this respect Vanua Levu contrasts strongly with Viti Levu. But Mr. Guppy thinks this scarcity to some extent the result of denudation, for he has found silicified corals, representing reef-forming types, lying about on the surface, abundantly in some places, together with nodules of chalcedony and other siliceous concretions. These, however, do not more than double the vertical range, so that during the actual building of the island circumstances were not favourable to reef-

[1] "Observations of a Naturalist in the Pacific between 1896 and 1899." By H. B. Guppy, M.B., F.R.S.E. Vol. i. Vanua Levu, Fiji. Pp. xix+392; illustrations and map. (London: Macmillan and Co., Ltd.; New York: The Macmillan Co., 1903.) Price 15s. net.

formation. It is possible, as Mr. Guppy explains, that the island even now is slowly rising.

A considerable part of the volume is devoted to the petrology of Vanua Levu. Plutonic rocks occur, though on a smaller scale than in Viti Levu. These are norites (hypersthene-gabbros) and a few diorites (without augite). The rest of the igneous rocks are volcanic, consisting of olivine-basalts, augite-andesites with and without hypersthene, and acid andesites passing into dacites, in which sometimes the ground-mass exhibits a felsitic structure. Mr. Guppy's careful study of these is a valuable addition to knowledge, though the volcanoes of Vanua Levu have not yielded any rock of exceptional interest. But we think he lays too much stress on varietal details, and that his "orders, suborders, genera and subgenera" have often no more than a specific value, and that he attaches too much classificatory importance to the presence or absence of phenocrysts (to follow him in using this modern petrological slang-word). They have an important relation to the history of the rock, but not very much to its chemical composition, and thus to its position among the magmatic products of the earth. A porphyritic rock is a "rock with a past," which a non-porphyritic rock either is free from, or successfully conceals. Mr. Guppy has "gone one better" than most modern terminologists. Throughout his descriptions he talks of felspar-lathes, meaning thereby the microliths, generally called lath-like. In English a lath means a long blade-like strip of wood, used, for instance, in ceilings, and not inaptly designating microliths of felspar, especially plagioclastic, while a lathe is a machine for turning wood, &c. We doubt also whether the formulæ which Mr. Guppy employs to summarise the characters of his rocks will be any real help to the memory, for they introduce the perplexities of gibberish without attaining the simplicity of mathematical symbols. Palagonite is very abundant at Vanua Levu, "from the sea border to the mountain top." Mr. Guppy discusses at some length the origin of this substance, coming to the conclusion that it is usually associated with basalt of an ophitic or semi-ophitic habit, is likely to be formed extensively on the surface of submarine basaltic flows, and is a vitreous condition of magma that remains fluid after the mass of the rock has solidified. An exceptionally hydrous state of a basic magma would probably be very favourable to the formation of palagonite, but whether the proposed petrological relation will hold generally good is perhaps doubtful.

But in expressing dissent on a few points, which are really of minor importance, we gratefully acknowledge that Mr. Guppy has accomplished a very laborious and often difficult, if not dangerous, task, and that his book, when completed by accounts of his botanical and other work, will be a most valuable addition to our knowledge of this group of islands and to the past geological history of a large area in the Pacific Ocean.

ELECTRIC CONVECTION.[1]

THIS paper closes in a satisfactory manner an important controversy. It follows from the views of Faraday and Maxwell that a charge of electricity when in motion produces a magnetic field in its neighbourhood. It is this effect on which the modern

[1] "Recherches Contradictoires sur l'Effet magnétique de la Convection électrique." Par MM. Harold Pender et Victor Crémieu. (*Journal de Physique*, September, 1903.)

electron theory of electric action rests; its experimental verification is vital to the theory, and, indeed, to the whole of the recent views, of the origin of electric and magnetic forces.

A method of testing the existence of the effect is given by Maxwell in his "Electricity and Magnetism," and was first put into practice, with some modifications, by Rowland in 1876. The experiment, carried out in Helmholtz's laboratory, proved to the satisfaction of Helmholtz and of Maxwell that the effect existed; this consisted in rotating a charged disc of gilded ebonite near an astatic magnetic needle and observing the deflection. This was very small, from 5 to 7·5 mm., but it agreed with the amount expected from the theory. In 1883 Lecher attempted to repeat these experiments, but with negative results; Röntgen, however, in a research having another object, obtained the same effect from a moving charge as Rowland had done. In 1889 Rowland and Hutchinson took the matter up, and, modifying the apparatus, obtained results which appeared to establish the convection of an electric charge on a moving conductor without a doubt.

In 1897 Crémieu began his experiments. If a charged moving conductor produces a magnetic field, a charged conductor at rest in a varying magnetic field should be subject to mechanical force. Crémieu failed to detect this force in an experiment arranged for its measurement, though, according to calculation, it ought, if existing, to have been easily measurable. He then attempted Rowland's reverse experiment, the detection of the magnetic field, but modified entirely and in an ingenious manner Rowland's arrangement. Imagine a coil placed in close proximity to the rotating disc, the planes of the two being parallel, and let the ends of the coil be connected to a galvanometer. On charging the disc a magnetic field is produced near the coil, if the Faraday-Maxwell views be true; thus a current is induced in the coil, and a throw of the needle of the galvanometer is the result. Then by arranging to charge and discharge the disc alternately, and by means of a commutator to reverse the galvanometer connections suitably, the throw becomes a permanent deflection the amount of which can be calculated. These experiments Crémieu carried out with consummate care, and the result was negative. The needle remained at rest; there was no such thing as electrical convection. This fact he verified apparently by several ingenious modifications of his apparatus and his method, always with the same result; and when at the Glasgow meeting of the British Association he gave an account of his work, probably no one in the room except himself accepted his results, but no one, and the critics were both acute and numerous, could find the flaw.

Meanwhile, Rowland had returned to the defence of his position; it was almost the last piece of work he undertook, and just at the time of Crémieu's visit to Glasgow, September, 1901, there appeared a full account of experiments in the Johns Hopkins Laboratory by Pender, who, adopting Crémieu's induction method, again verified Rowland's result. From the observations a value can be found for the velocity of light, and Pender found it to be $3·05 \times 10^{10}$ cm. per second, a value sufficiently near to the truth to establish beyond a doubt the theory of the measurements. This was verified by further work published early this year; meanwhile, Crémieu continued to obtain his negative results.

Such was the position when Pender was invited to Paris to repeat, in the splendid laboratories of the Sorbonne, and in conjunction with Crémieu, the experiments he had made in Baltimore. Funds were provided, in part by the Carnegie Institution, in part by the Institute of France, and the two experimenters set to work together, and with the same result—Pender verified the Faraday-Maxwell theory, Crémieu disproved it.

Experiments were then made on the direct magnetic effect, repeating, but with some modifications to meet objections of Crémieu, Rowland's original experiment. These, again, led to the result that a charged surface moving in its own plane produces a magnetic field; the very sensitive and permanent astatic system employed in this experiment will be found useful elsewhere, but reference must be made to the original paper for an account of it. Finally, Crémieu was convinced; it remained only to account for his negative results.

It was observed that in all cases he had covered the charged conducting surfaces with a thin layer of some dielectric other than air, usually india-rubber or mica, and there seemed some reason to suppose his failure was due to this, and so it was proved to be; the removal of the dielectric coating from Crémieu's apparatus enabled him to observe the convection effect, while by coating the discs used in Pender's induction experiment with mica, the convection effect was reduced by some 90 per cent.

How the dielectric acts is still a mystery; it is satisfactory, however, that the two experimenters are in agreement. The thanks of physicists are due to those who suggested and rendered possible this somewhat novel collaboration; it is satisfactory to the great French physicists who have aided Crémieu with advice and assistance that the matter should be settled at Paris; it is satisfactory to Pender that he has established conclusively and finally the result which was the beginning of Rowland's brilliant fame.

At the same time, the question, What does the dielectric do? remains an interesting one, especially as Vasilesco-Karpen, in a paper which follows the one we have been discussing, finds that it has no effect on the result. He modified Crémieu's arrangement by introducing a condenser into his circuit of coil, commutator and galvanometer, in which induced currents are set up by the alternating charge and discharge of the rotating discs. By suitably arranging the period of this circuit he was able to intensify the efforts considerably, and obtained a reasonably satisfactory agreement between his results and theory. The disc, as was the case in most of Pender and Crémieu's experiments, moved between condensing plates, and Vasilesco-Karpen made the following four series of experiments:—(1) Disc bare, condensing plates bare; (2) disc bare, condensing plates covered with glass 4 mm. in thickness; (3) disc covered with a thin layer of caoutchouc, condensing plates bare; (4) disc as in (3), condensing plates as in (2).

He states as the result that, so long as the speed and the charging voltage are kept constant, the magnetic effect is the same in all these cases. This result is opposed to that of Crémieu and Pender, who found that coating the disc with a thin layer of rubber destroyed the convection effect, and so the matter rests at present. The magnetic effect due to the motion of an electron is confirmed; some of its secondary consequences remain obscure.

NOTES.

The list of birthday honours includes the following names of men known in the scientific world:—Prof. C. Le Neve Foster, F.R.S., has received the honour of knighthood. Colonel D. A. Johnston, director-general of the Ordnance Survey, has been appointed a Companion of the Order of the Bath. Dr. Robert Bell, F.R.S., acting director of the Geological Survey of Canada, has been appointed a Companion of the Imperial Service Order. The

Hon. A. C. Gregory, formerly surveyor-general of Queensland, who has done much for exploration and the promotion of science in Australia, has been promoted to the rank of K.C.M.G.

The following is a list of those to whom the Royal Society has this year awarded medals. The awards of the Royal medals have received His Majesty the King's approval:—The Copley medal to Prof. Eduard Suess for his eminent geological services, and especially for the original researches and conclusions published in his great work "Das Antlitz der Erde"; a Royal medal to Mr. Horace T. Brown for his work on the chemistry of the carbohydrates, and on the assimilation of carbonic acid by green plants; a Royal medal to Sir David Gill for his researches in solar and stellar parallax, and his energetic direction of the Royal Observatory at the Cape of Good Hope; the Davy medal to M. Pierre Curie and Madame Curie for their researches on radium; the Hughes medal to Prof. J. Wilhelm Hittorf for his experimental researches on the electric discharge in liquids and gases.

We are informed that Dr. Charles J. Martin, F.R.S., has now entered upon his duties as director of the Lister Institute of Preventive Medicine, and in future the administrative work of the Institute will be under his control.

The annual course of Christmas lectures at the Royal Institution, specially adapted to young people, will be delivered by Prof. Ray Lankester, F.R.S., whose subject is "Extinct Animals." The first lecture will be given on Tuesday, December 29.

An application has been made by the German Meteorological Office for daily telegraphic reports from the Ben Nevis Observatory, with the view of applying them in forecasting the weather of north-western Europe. The directors of the observatory have agreed to send the telegrams asked for.

Many biologists will regret to know that Mr. I. C. Thompson, well known as a naturalist, and especially for his work in connection with the Liverpool Marine Biology Committee, died suddenly on November 6.

Prof. Raphael Pumpelly, of Newport, R.I., and Prof. W. M. Davis, of Harvard, have returned from a journey in Turkestan, made under the auspices of the Carnegie Institution, to study the ancient human occupation of the region in relation to its physiography. *Science* states that the expedition proceeded from Baku to the end of the main line of the Central Asiatic Railway at Tashkent. Prof. Pumpelly, with one party, then made an excursion south-eastward across the Alai range and valley to Lake Karakul on the northern Pamir. Prof. Davis and his party went north-east, crossing the western Tian Shan ranges to Lake Issikul.

It is reported in some of the daily papers that Dr. Otto Schmidt, of Cologne, has succeeded in isolating and cultivating a parasite from cancer, and in preparing an antiserum for the disease. So many positive statements of the isolation of a cancer-parasite have been made during the last few years, and have subsequently proved to be incorrect, and so many capable men have been investigating cancer without result, that reports of this kind cannot be accepted without further proof. The publicity given to matters of this kind is much to be deprecated; in the majority of instances false hopes are raised which must end in disappointment for many sufferers.

Lieut.-Colonel Bruce, who has been investigating sleeping sickness in Uganda, has returned to England, having confirmed and extended the observations of Castellani upon the presence of a trypanosome parasite in this disease. The trypanosome was found to be present in practically every case in the cerebro-spinal fluid, and also in the blood. From analogy with nagana or tsetse fly disease of horses and cattle, it was surmised that a species of tsetse fly might carry the infection in sleeping sickness, and along the shores of the Lake Victoria Nyanza, where the disease is especially rife, large numbers of a tsetse fly (*Glossina palpalis*) were found, and were demonstrated by experiment to be capable of carrying the trypanosome. Moreover, freshly caught flies in infected areas were in some instances found to harbour trypanosomes. It is further suggestive that this fly is confined to certain well-defined areas which correspond absolutely with the distribution of sleeping sickness; in regions where no *Glossina palpalis* is found there is no sleeping sickness. These investigations therefore point to the conclusion that sleeping sickness is a human tsetse fly disease.

At the Royal Geographical Society on Tuesday Commander Peary gave an address on his "Four Years' Arctic Exploration, 1898–1902." In the year 1899 he obtained the material for an authentic map of the Buchanan Bay, Bache Peninsula, Princess Marie Bay region, crossed the Ellesmere Land ice-cap to the west side of that land, established a continuous line of caches from Cape Sabine to Fort Conger, and familiarised himself and party with the entire region as far north as Cape Beechey. During the journey in 1900 Commander Peary determined conclusively the northern limit of the Greenland archipelago, or land group, and practically connected the coast south-eastward to Independence Bay, leaving only that comparatively short portion of the periphery of Greenland lying between Independence Bay and Cape Bismarck indeterminate. The non-existence of land for a very considerable distance to the northward and north-eastward was also settled, with every indication pointing to the belief that the coast along which the party travelled formed the shore of an uninterrupted central polar sea extending to the Pole, and beyond to the Spitsbergen and Franz Josef Land groups of the opposite hemisphere. In 1901 Commander Peary left Conger for another northern trip, but on reaching Lincoln Bay it was evident that the condition of men and dogs negatived the possibility of reaching the Pole, so the party returned to the *Windward* at Payer Harbour. In 1902 a start was made from Payer Harbour for the northern journey, and latitude 84° 17′ 27″ N. was reached, but the party had to return, and in the autumn of the year the *Windward* steamed southward, arriving at Sydney, C.B., on September 17, 1902, after an absence of four years, three months, and ten days. Referring to his future plans, Commander Peary said he hoped to start north next July, and if the season was favourable he would have his ship by September 1 on the northern shore of Grant Land, near the *Alert's* winter quarters. Wintering there, he would start with the first of returning daylight in the following February to make a journey across the polar pack to the Pole and back again.

Major Ronald Ross read a paper on malaria in India and the colonies at the Royal Colonial Institute on Tuesday. In the course of his address he pointed out that scientific research has established three great laws concerning malaria:—first, that it is caused by numbers of microscopical parasites which live and propagate themselves in the blood; secondly, that these parasites are carried from sick persons to healthy ones by the agency of a genus of

mosquitoes called Anopheles; thirdly, that these kinds of mosquitoes breed principally in shallow and stagnant terrestrial waters. Four years have elapsed since these facts were established, and a vast mass of information has been accumulated regarding the actual working of the preventive measures which have been based upon them. Major Ross described the State measures for the repression of malaria that have already led to successful results in Sierra Leone, Havana, Lagos, Ismailia, the German colonies, Hong Kong, and other places. It has been proposed that permanent sanitary commissioners should be appointed for some of the colonies, but Major Ross said that Mr. Chamberlain has suggested to him an alternative scheme, namely, that several learned societies should periodically be asked to send out special commissioners for the purpose of examining and reporting upon the sanitary affairs of specified tropical Crown colonies, and that such reports, after editing by the societies referred to, might then be submitted to Government for consideration. Commissioners of this kind would cost less, and, not being servants of Government, would be able to give entirely unprejudiced opinions.

A DEMONSTRATION was given last week at the works of Messrs. Johnson and Phillips of a new electrical process for the preparation of peat-fuel. The process aims at extracting the large percentage of water in peat, partly by mechanical and partly by electrical means; the freshly cut peat is packed into rotating cylinders, and whilst fans beat out part of the moisture, a strong current of electricity is passed through the mass which heats it and thereby helps the extraction of the water. It is claimed that a first-class fuel can be produced in this way, but no particulars as to the cost of production, or results of tests of the fuel by competent engineers, are given in the pamphlet describing the invention.

THE Nagri Sabha established in Benares has, we learn from the *Pioneer Mail*, interested itself in making additions to the Hindi literature, but the difficulty of translating English scientific works, on account of the absence of suitable Hindi equivalents for the English technical terms, has been an obstacle in the way of authors. The Sabha, therefore, resolved to remove this difficulty by compiling, with expert aid an authoritative dictionary of scientific words and phrases met with in the English scientific works, and separate glossaries were ready last year and circulated for criticism among men of science in India. In order finally to approve and pass the tentative lists, the Sabha appointed a committee from among its members, and invited the various local Indian Governments to nominate representatives. Criticisms have been received from men of science in various parts of India.

THE medical officer of health for the City of London states in his last report that a case of enteric fever has been notified from Paddington as having in all probability been caused by mussels sold in Billingsgate Market. The mussels were found to have been obtained from a dealer at Leigh-on-Sea, and in consequence samples of mussels and cockles from the same source were submitted to Dr. Klein for bacteriological examination. Dr. Klein reported that both the cockles and the mussels were polluted with sewage, some of them to a dangerous extent, and that the cooking of the molluscs had been very imperfectly carried out. This state of affairs having been brought to the notice of the Fishmongers' Company, the sale of cockles from Leigh has been prohibited in the London markets. Some months ago the Leigh cockles were found to be polluted, and warnings were issued and directions given for a minimum period of boiling to be adopted, which seem to have been disregarded.

A VERY interesting lecture, entitled "Allerlei Methoden, das Wetter zu prophezeien," delivered by Prof. J. M. Pernter, director of the Austrian Weather Service, before the Society for the Diffusion of Scientific Knowledge, Vienna, has recently been published by that Society. As the title suggests, the author deals with all kinds of methods employed for weather prediction from the earliest to the present time. After doing full justice to the usefulness of local weather signs, such as the appearance and movements of clouds, the formation of caps on hills, the colour of morning and evening skies and the like, often successfully interpreted by agriculturists and others, he gives particular attention to *a priori* theories based on cycles, the phases of the moon, and the motions of planets, and points out their general untrustworthiness, and the great difference between such theories and the empirical inductive methods adopted by the meteorological central offices. By these latter means only can any advance be made. With the knowledge which at present exists, however, he holds out little hope of being able to forecast the weather for more than one day in advance. To improve upon the results now obtained, the author points out that a more minute investigation is required (1) of each point of every form of distribution of barometric pressure; (2) of the rate and direction of travel of each depression over Europe; (3) of the manner in which a certain type merges into another form; and (4) of the change in the weather caused by the various modifications of each form of barometric distribution. By a careful study of such details the author thinks that the percentage of total successes of the forecasts may be gradually raised.

IN the *Proceedings* of the American Academy of Arts and Sciences, Prof. R. W. Wood discusses the anomalous dispersion, absorption, and surface colour of nitroso-dimethylaniline. This substance is interesting as filling the gap that exists between the aniline dyes and ordinary transparent substances.

M. CH. FÉRY describes in the *Journal de Physique* a convenient method for determining the constants of lenses. It depends on the principle that if a ray falls on a lens in a direction parallel to the axis, and at a distance d from it, it will undergo an angular displacement α, the tangent of which is d/f, where f is the focal length, and by observing α, f can be found. Moreover, by calculating the values of f corresponding to different values of d, the aberration can be calculated.

MANY attempts have been made to give purely dynamical proofs both of Maxwell's law and of the second law of thermodynamics, but nearly every one of these deductions has, on closer examination, been found to involve some assumption or other, and not to be a result of mathematical reasoning alone. In two recent communications to the *Philosophical Magazine* (August and October) Mr. S. H. Burbury discusses the late Prof. Willard Gibbs's treatise on statistical mechanics and Mr. J. H. Jeans's theory of gases, and his criticisms go to show that these investigations form no exceptions to the rule.

THE *Scientific American* for October 10 contains two papers of interest in connection with the problem of "aviation." M. Émile Guarini describes some experiments by Prof. Bertelli for studying the action of air currents on curved surfaces such as may be taken to represent birds' wings, and a new aëroplane machine, con-

structed by Messrs. Groombridge and South, is described, which is stated to be 80 feet long and 60 feet wide (the figure of the "full-sized model" hardly corresponds to these dimensions), and is to be supported on two sets of superposed aëroplanes, one at the front and the other at the rear of the machine.

IN his fifth report on seismological investigations presented to the British Association at Bradford, Prof. Milne directed attention to the connection between large earthquakes and variations of latitude indicated by a comparison of the statistics for the period 1895–1898. Mr. Adolfo Cancani has published in the *Bolletino* of the Italian Seismological Society the corresponding figures for 1899–1902, and the results tend to confirm Prof. Milne's hypothesis. The figures for 1895 and 1896 give a smaller number of earthquakes satisfying the conditions laid down by Mr. Cancani than would be required on the hypothesis of such a connection, but this the author attributes to the fact that the arrangements organised by Prof. Milne for recording seismological observations were not completed in the two years in question.

WE have received from the makers—Messrs. Newton and Co., 3 Fleet Street—an extremely simple device called the "Boyla" tube, which has been designed for the purpose of demonstrating all the phenomena attendant upon the processes of ebullition and condensation. It consists of a strong glass tube about four inches long and three-eighths of an inch in diameter, in which a readily vaporisable liquid is hermetically sealed. When held over a very small flame the liquid boils, and when its temperature reaches the critical point the surface rises and becomes ill-defined; then the liquid vaporises and forms clouds in the upper portion of the tube, which in turn condense and form drops that fall through the space above the liquid in the form of rain. Thus the whole process of ebullition and condensation may be shown to a number of students at one time, and in a much more convenient manner than is at present in general use. The tube is bent round at the top in the form of a hook, so that it may be readily suspended over the flame, and, in the absence of accidents, it may be used over and over again *ad libitum*.

THE author of the article on "Botany at the British Association" in NATURE for November 5 writes to say that the last line of the paragraph dealing with Miss Sargant's paper on the origin of the Monocotyledons (p. 18) should read, "it was more like a Dicotyledon than a Monocotyledon." In his report he inadvertently transposed the words Dicotyledon and Monocotyledon.

THE September issue of the *American Naturalist* contains a continuation of Prof. Morse's synopses of North American invertebrates, this section dealing with the parasites of the genus Trichodectes, which infest mammals.

IN the October number of the *Zoologist* Mr. J. L. Bonhote records the existence of a British example of the mouse-coloured bat (*Myotis murinus*), taken at Girton in 1888. The specimen was probably brought over from the Continent with plants or other produce. The only other record of the species in our islands is afforded by some specimens taken in the grounds of the British Museum previous to 1855.

A PAPER in the October issue of the Zoological Society's *Proceedings* on "The Marine Fauna of Zanzibar and British East Africa," by Mr. F. F. Laidlaw, deals with the planarians of the Zanzibar district, in which, out of a total of nine species collected, eight are described as new, four of them being referred to new genera. Apparently no shore-haunting species have hitherto been recorded from the eastern side of Africa, except in the Red Sea and Cape Colony, hence the high percentage of novelties.

UNDER the title of "Cold Spring Harbor Monographs," the Brooklyn Institute has commenced the issue of a series of short animal biographies after the plan of the well-known "L.M.B.C. Memoirs." Of the two issues before us (forming the first and second of the series), the one, by Miss Smallwood, deals with the beach-flea or sand-hopper (*Talorchestia longicornis*), while the second, by Mr. Davenport, is devoted to the local representatives of the insects of the group Collembola, with special reference to the movements of the section included in the family Poduridæ. Both memoirs are illustrated with plates, which are perhaps a little rough in execution.

DR. O. ABEL, in the *Sitzungsberichte* of the Royal Vienna Academy, describes certain isolated molars of anthropoids from the Leithakalk. One of these, for which the name *Griphopithecus suessi* is suggested, indicates a new generic type, while the other is assigned to Dryopithecus, with the title *D. darwini*. It is also pointed out that the name *Arthropodus*, proposed by Dr. Schlosser last year for certain anthropoid remains, is preoccupied, and the name *Neopithecus* is suggested in its place. In the same journal Dr. F. Werner describes the reptilian and amphibian fauna of Asia Minor. Special attention is devoted to the true lizards (Lacerta), which are illustrated in three coloured plates, one form being described as new, under the name of *L. anatolica*.

A RECENT *Bulletin* of the New York State Museum is devoted to an account, by Dr. J. L. Kellogg, of the feeding habits and growth of *Venus mercenaria*, commonly known as the "little-neck clam." In his introductory remarks the author directs attention to the rapid diminution in the number both of that species and of the true "clam" (*Mya arenaria*), both of which form important articles of diet in New York. "Clam-farming" would undoubtedly long ago have taken the place of "clam-digging" were it not that beaches and sand-flats are public property to which everyone has the right of access. The little-neck clam, although it will also flourish between tide-marks, grows most abundantly below low-tide mark, where it is taken with tongs. "Much of the shallow bottom about Long Island, in which clams were formerly taken, has been leased to oystermen. The profit from oyster culture is much greater, acre for acre, than that derived from the taking of hard clams, which are left to propagate by the natural method. The areas left to clammers are now limited, and the great part of the supply used in the canning industry comes from the southern coast. At the same time clams are rapidly diminishing in the available beds."

THE new cone of Mont Pelée and the gorge of the Rivière Blanche, Martinique, are dealt with by Mr. E. O. Hovey (*Amer. Journ. Science*, October). He directs special attention to the new "spine" or obelisk of which an illustration was given in NATURE for October 1. Mr. Hovey remarks that no one can say exactly what the nature of the spine is, but probably it is largely pumiceous. Another striking feature is the filling of the gorge of the Rivière Blanche with calcined rocks, dust, and ashes which have been poured out of the crater by numerous eruptions.

THE National Transcontinental Railway is planned to extend to the north of the Canadian Pacific Railway, from New Brunswick through Quebec and Ontario to Winnipeg, in Manitoba. There it meets the Canadian Pacific Railway, and diverges again to the north, through parts of

Assiniboia, Saskatchewan, Alberta, and Athabasca, and across British Columbia to the neighbourhood of Port Simpson. In aid of this enterprise a concise report on the resources of the line of country between Quebec and Winnipeg has been drawn up by Dr. H. M. Ami, of the Geological Survey of Canada (Sessional Paper, No. 143). The physical geography, geology, soils and economic minerals, and the natural history generally are described.

In some notes on the geology of the Hawaiian Islands (*Amer. Journ. Science*, October), Mr. J. C. Branner directs attention to the striking series of canyons in the volcanic rocks on the northern coast of Hawaii. There are bluffs with an elevation of a thousand feet, and enormous gorges that extend inland with almost perpendicular walls, some of which are said to be 2000 feet in height. The gorges are nearly or quite as deep near their upper ends as at the lower ends, and they have flat bottoms. They were formed as V-shaped gorges on the land, and have sunk until their lower ends were occupied by the sea, forming deep fjords which were soon filled by material derived partly from the sea and partly from streams. Other interesting features are dealt with by Mr. Branner.

A full account of the life and work of the late Prof. Cornu is contained in the *Revue générale des Sciences* for October 30. The appreciation is from the pen of M. C. Raveau.

The lecture on the periodic system of the elements delivered by Sir William Ramsay at the recent meeting of the German Association at Cassel (see Nature, October 15, p. 586) has been published in pamphlet form by the firm of J. A. Barth, Leipzig.

Among articles dealing with scientific subjects contained in the November reviews and magazines, we notice two dealing with recent experiments on radium. One is by Mr. J. B. Burke on the radio-activity of matter, and is contained in the *Monthly Review*, the other, on the riddle of radium, is by Mr. A. S. M. Hutchinson, and is published in *Pearson's Magazine*. The latter magazine gives considerable prominence to science this month, for in addition to the article mentioned, there is one on "Our Descent from Monkeys," by Mr. S. S. Buckman, illustrated by photographs showing habits and characteristics that link man to monkey forms, and also descriptive accounts of the Waimangu geyser, New Zealand, and the habits of woodcocks.

A paper read by Mr. Edmund McClure at the Church Congress held at Bristol last month is a satisfactory indication of the sympathetic attitude which the churches now show towards scientific research. Mr. McClure's paper was entitled "The Aids which Science gives to the Religious Mind," and in it, after referring to Mendeléeff's periodic law and the recent work of Sir W. Crookes and Sir W. Ramsay, he asks:—"Does not the religious mind, which lives and moves in the sphere of the unseen, find an aid in such an extension of the reach of the mental eye?" It is encouraging to know that scientific work and thought can inspire reflections on the relation between the visible and invisible universes.

Messrs. Townson and Mercer, of Camomile Street, London, have submitted to us for examination a form of extensimeter designed by the Rev. G. B. Lavelle, of Waterford. The method of measuring linear expansion upon which the construction of the apparatus depends, is already well known in physical laboratories, and the apparatus is an elaborate form of one described in elementary books on practical physics. The instrument consists of a brass cylinder half a metre long, with side tubes for the ingress and egress of steam. The half-metre metal rod of which the linear expansion is to be determined rests on the bottom of the cylinder, and its other end passes through a hole in a movable metal cap to the cylinder. Temperatures are measured by thermometers introduced through india-rubber stoppers in the side tubes, and the spherometer is supported on a brass plate with a hole in the centre, the plate being so supported that it and the spherometer can be moved away from any issuing steam. A dry cell and electric bell are supplied with the apparatus to provide for greater accuracy in determining the instant of contact between the spherometer and the metal rod, but this seems an unnecessary elaboration.

High vacua for distillation under reduced pressure can be rapidly produced by filling the apparatus with carbon dioxide and condensing this with liquid air. Liquid carbon dioxide cannot be used, as it contains 0·75 per cent. by volume of dissolved air, but carbon dioxide snow gave good results; the dissolved air, like that dissolved in water, contains an excess of oxygen, the proportion being 24·1 per cent. by volume. The most convenient method is to prepare the gas from marble and hydrochloric acid, and to exhaust to 30 mm. by means of a water-pump; this operation is repeated four times, and on cooling with liquid air a vacuum of 0·1 mm. is produced. The lowest pressure recorded was 0·026 mm. when rubber connections were used, but in a vessel made wholly of glass the vacuum required for the production of kathode rays could be obtained. Ernst Erdmann, in describing this method in a recent number of the *Berichte*, adds that in London liquid air costs less than fivepence per kilo.

The additions to the Zoological Society's Gardens during the past week include a Ring-tailed Lemur (*Lemur catta*) from Madagascar, presented by Lady Campbell; a Grey Seal (*Halichoerus grypus*) from the West Coast of Ireland, two Meyer's Parrots (*Poeocephalus meyeri*) from South-east Africa, two Yellow-billed Cardinals (*Paroaria capitata*) from Chili, five Bungoma River Turtle (*Emyda granosa*), three Roofed Tortoises (*Kachuga tectum*), three Indian Eryx (*Eryx johni*), four Conical Eryx (*Eryx conicus*) from India, a Four-lined Snake (*Coluber quatuorlineatus*), South European, deposited; a Polar Bear (*Ursus maritimus*) from Nova Zembla, purchased.

OUR ASTRONOMICAL COLUMN.

Revision of Rowland's Wave-lengths.—In view of the extreme importance to workers in astrophysics of having a perfectly trustworthy system of standard wave-lengths, Prof. Hartmann reviews, in No. 3, vol. xviii., of the *Astrophysical Journal*, the methods used by Rowland in constructing his wave-length tables, and points out their sources of error. He shows that Rowland made the metallic arc wave-lengths given in his "New Table of Standard Wave-lengths" coincide with those of the solar spectrum by applying purely empirical corrections which cannot now be found. In a series of tables Prof. Hartmann also shows that differences, amounting in some cases to 0·03 unit, exist between the solar and metallic wave-lengths, and suggests that further experiments should be performed, on similar lines to those pursued by Michelson and Fabry and Perot, for the purpose of determining a general factor—the F of Fabry and Perot—by which the whole of Rowland's table might be reduced to a rationalised standard from the equation $\lambda = (F \text{ and } P)Fo$, where (F and P) is the absolute wave-length found by the French observers, and Fo is the factor mentioned above. This would produce an errorless wave-length on Rowland's scale for each of the thirty-three lines measured by Fabry

and Perot, which would vary but little from Rowland's values, and yet be free from their systematic errors.

Prof. Hartmann has already done this for the part of the spectrum on which Fabry and Perot worked, and has obtained a correction, C, which, when applied to the values given in Rowland's "Preliminary Table," rids them of the errors discussed by him. Not having the necessary facilities for pursuing this important work himself, Prof. Hartmann appeals to those spectroscopists who have them to complete the work commenced by Michelson, Jewell, and Fabry and Perot for the whole of Rowland's tables.

PARALLAX OF β CASSIOPEIÆ.—In a note to No. 3910 of the *Astronomische Nachrichten*, Herr S. Kóstinksky, of Pulkowa, discusses the results of three separate determinations of the parallax of β Cassiopeiæ. The first of these was obtained by Prof. Pritchard, using the photographic method, at Oxford in 1888, and gave the value $\pi = +0''\cdot15 \pm 0''\cdot02$; the second, obtained by Herr Kóstinksky himself, using the transit instrument in the prime vertical, gave a mean value of $\pi = +0''\cdot14 \pm 0''\cdot03$, whilst the third was recently obtained by Mr. A. S. Flint, of the Washburn Observatory, from meridian-passage observations, and produced as the mean result $\pi = +0''\cdot10 \pm 0''\cdot03$.

On considering these three values, obtained by three different methods, Herr Kóstinksky arrives at the conclusion that the absolute value of the parallax of β Cassiopeiæ is with great probability very near to $+0''\cdot1$, and rather a little greater than less.

ASTRONOMY IN SCHOOLS.—Mr. W. W. Payne contributes an interesting article to No. 108 (October) of *Popular Astronomy*, in which he strongly advocates the introduction of practical yet simple astronomical observations into the ordinary higher grade school's curriculum. He points out the absurdity of the general opinion that large instruments and expensive equipments are necessary in order to render observational astronomy a truly educative subject, and shows that a large amount of real training of the observational powers might be given with a small telescope. As examples of the type of observation he would suggest, he mentions the recognition of the brighter stars by name, and the keeping of methodical records of their light and colour characteristics and their occasional changes. Then, with quite a small telescope, a large amount of useful work—from an educative point of view—might be performed in observing and methodically recording the characteristics of some of the finer examples of multiple stars.

UNIVERSITIES: THEIR AIMS, DUTIES, AND IDEALS.[1]

VARIETY OF TYPES OF UNIVERSITIES.

ONE remark of a general kind must be made before proceeding to a synthesis of the purposes of universities. It is a platitude, yet not unimportant, to the effect that they will not be (and cannot be expected to be) uniform in character. Old universities have their traditions, sometimes the growth of centuries; and though they have to review their ideals from time to time and to revise their practice to meet the challenges and the demands made by the growing needs of the nation, changes are made only gradually, and the main character tends to persist through the changes. On the other hand, new universities arise in response to new demands of diverse kinds, and their character is bound to be shaped by their origin, their circumstances, and their growth. In the later Middle Ages, the philosophy of the schoolmen yielded before the onset of the study of the humanities—a study which has largely determined the character of our oldest universities. The physical sciences, by their growth during the last century, have modified the range of education and have influenced profoundly some of the older universities, while they have had no small share in dominating the form of newer foundations. The needs of applied sciences and practical sciences in our own day are stirring ideals of education widely removed from those that reposed upon the humanities, and they are leading to the establishment of learned institutions of types hitherto unknown. Sometimes between one university and another, sometimes within the limits of a single university, there will be what is almost a struggle among the subjects in their historical assignment to courses of study. Fundamental questions are being asked. Should the study of modern languages displace that of the ancient languages? Will applied science diminish the attention paid to pure science? Will practical needs direct the study of applied science? Must the acquisition of so-called useless knowledge be renounced in favour of so-called useful knowledge? Can it still be possible to maintain the process of a liberal education in the presence of the demands for technical instruction and commercial instruction? These and many other questions will arise in practically every university. They must be answered when they arise, and the answers will vary, perhaps from time to time, certainly from body to body. Yet diversity of character, of circumstances, and of practice, will not exclude a certain community of spirit and a certain similarity of obligation.

[1] Part of an address to the Southport Literary and Philosophical Society, delivered on September 17 by Prof. A. R. Forsyth, F.R.S.

WHAT IS A UNIVERSITY?

What is a university? Is it a building, or a set of buildings? Is it a federation of schools? Is it an aggregation of faculties? Is it a corporation of individuals, formally devoted to a common purpose? Is it an examining body with power to grant degrees? In each of these senses, and doubtless in several others, the word university has been vaguely used at different times and of different bodies. In its earliest use in regard to the kind of institution under consideration, a university appears to have been a sort of scholastic guild; there were societies of masters, as there were societies of students, and each of these was called a university. There were two places where these guilds grew into greater importance than elsewhere at the close of the twelfth century; one was Paris, mainly a university of masters, the other was Bologna, mainly a university of students. Indeed, so supremely important were these two universities, even while they were so distinctively different in character, that most of the older European universities have conformed to one or other of these types in many (if not in most) essential features. Thus Oxford and Cambridge are modelled on the master university of Paris; it is the graduates who have the power of electing the acting chief of the university. On the other hand, the ancient Scottish universities are modelled on the student university of Bologna; it is the undergraduates who have the power of electing the acting chief of the university. There have been variations in the detailed developments of the different universities. Most of them had several faculties, though not all of them had the same faculties. Thus Salerno, at the zenith of its fame towards the end of the eleventh century, was simply a medical school (having, it may be mentioned, several women among its teachers and writers). Bologna had a faculty of law only; Paris had faculties of theology and arts; Saragossa had one of arts only. The notion that a university was a school in which all branches of knowledge are represented was one that sprang up later, and had a considerable vogue; this Literary Society will readily recall Dr. Johnson's description of a university as "a school where everything may be learnt." The conception of a university as a centre for the cultivation of universal knowledge and the teaching of universal knowledge undoubtedly propounds a stimulating ideal, and the realisation of the ideal is as nearly imperative in modern times as anything almost impossible can be. At any rate, I know of no instance in which that conception of a university is justified by actual facts; and there is on record one instance in which the conception was completely falsified by actual facts, in that no teaching of any kind of knowledge whatever was done—the old university of London, now modified into a university that not merely examines, but also teaches.

CHARACTERISTICS.

What, then, should be taken as the working conception of an ideal university? To my mind, it is a corporation of teachers and students, banded together for the pursuit of learning and the increase of knowledge, duly housed, and fitly endowed to meet the demands raised in the achievement of its purposes. In the prosecution of its academic

aims, the university should be free from all external censorship of doctrine; it should also be free from all external control over the range, or the modes, or the subjects, of teaching. Above all, thought should be free from fetters of official type: whether political, from the State; or ecclesiastical, from the churches; or civic, from the community; or pedantic, from the corporate repressive action of the university itself. In its establishment, the amplest powers that wisdom can suggest should be conferred upon it. In working out its intellectual salvation, the exercise of those powers should be vested in select bodies of fit persons, sufficiently small in number to be efficient, yet large enough in number to prevent degeneration into an intellectual clique, changing sufficiently from time to time to prevent the dominance of merely personal policies, and representative enough to be in touch alike with the experience of the past and with aspirations for the future so far as these have taken shape or have acquired definition.

Access to the facilities of the university should be open to all duly qualified persons, without consideration of sex, without consideration of station in life, without consideration of intellectual beliefs, whether theological, political, or otherwise. The university should have the power of requiring both a minimum of qualification and a variety of qualifications to be satisfied by an applicant before admission to the status of student. Some test of qualification had to be imposed upon mediæval students, for Latin, then still something of a living language, was the one language of learning—and workers in science can sigh that it ever ceased to be so. That some test of qualification still is desirable probably is obvious to anyone who accepts my view of what university education should be. In my view, the school should prepare for the university, and education in the university should be, not something distinct from the school education, but rather its development, its amplification, and (on some issues) its complement. Briefly stated, the preliminary training should have been finished, and only those whose attainments show that they are qualified to profit by further training should be admitted to the courses of university study.

Qualification of Students.

As this limitation is important, will you be patient with me while I make a digression from my main topic and indicate the kind of minimum of qualification that I, if an autocrat, should exact in order to have one security (necessary, though not sufficient) that the students shall be not unworthy of a seat of learning? Besides the usual elements of reading, writing, and arithmetic (and I would add drawing to them), his studies should have included subjects that would train and develop some power of expression, some power of reasoning, some power of observation. To give him some power of expression, I would use his own language in the first place, initiating him into the mysteries of grammar and analysis through it alone, giving him some acquaintance with selections from the best of its literature, and, above all, practising him regularly in the art of composition in his own language. Then, after a certain stage, and in order to give him, while still at school, a more accurate literary training, he should be drilled in at least one foreign language, so as to be able to read it with ease and accuracy; the contrast of the two languages in idiom, diction, method, and manner, should emphasise his critical appreciation of his own, and increase, therefore, his control over it. If he can spare time for only one foreign language, my choice would be a modern language; if he can spare time for two foreign languages, let Latin be one of them; if he can spare time for more, he is in the way of being a scholar, and he needs none of my presumptuous directions on this head. To give him some power of reasoning, I would use the elements of mathematics; his algebra should be built upon his arithmetic, without the fatuous artificialities that disfigure text-books and examinations, though happily in a lessening degree; above all, he should have a training in geometry, beginning with experimental work so as to familiarise him with the matter, and gradually introducing the processes of geometrical reasoning; and if he can be taught the elements of mechanics, beginning also with an experimental basis, so much the better. To give him some power of observation, I would use some of the experimental sciences; my own choice would be the rudiments of experimental physics or inorganic chemistry. But more than all these are wanted; all the studies thus far prescribed are for the purpose of sharpening his wits, and, in the process, they will develop his intelligence. The latter must be developed also in other ways, and to my mind one of the best of ways is to give him a general knowledge of the history of his country, a general knowledge of the geography of the world, and (if possible) some rudimentary knowledge of the modern history of neighbouring countries.

Such a programme provides the elements of a liberal education. A youth, so educated, is ready for the technical training now needed for so many of the occupations of life, and even if he does not devote more time to the continuance of his studies, he is provided with the elements of such intellectual interests as should make him an intelligent man and an intelligent citizen. Also, such a programme is practicable for the average boy; no exceptional ability is needed to have completed such a course at the age of fifteen or sixteen. I am not prepared to say that the average boy at any school in England will have achieved this programme before he is sixteen; if I may judge from some not entirely laudatory criticisms that are openly expressed from time to time and remain unrebutted, it seems to be the fact that the average boy at a public school does not achieve such a programme or its equivalent before he is sixteen. But I am optimistic enough to believe that, in the future as in the past, improvements can come even in English education, and meanwhile I am content to claim that the programme of training which has been sketched is not merely possible, but is practicable also, within the time allowed.

Groups of Students.

Let us assume, therefore, that we have an ample supply of average students who have undergone some not inadequate preliminary training, and, as hopeful assumptions are encouraging, let us further assume that there is more than a sprinkling of students with abilities well above the average. In coming to our ideal university, which is eager to receive them, the students are actuated by varied kinds of needs and desires. Some—many of them, I should like to think—mean to devote themselves to one or other of the different forms of practical business, not intending to use their university education professionally, but preparing to take their part in maintaining and elevating the tone of the community. All the professions and callings, whether learned or technical, are to be recruited from among the students when once they have been trained. Some have the intellectual ambition, more or less defined as yet, ultimately to devote themselves to a life of learning in their own university by preference, yet, if not there, then in some other. There are men intent upon the ministry of religion; there are men intent upon the public service of the State. Last in this enumeration, there are the men of genius, as yet unproclaimed, who are to find in the university that training which will gradually reveal to them their powers, and that stimulus which will inspire them to the highest service of mankind as the discoverers and the thinkers of their generation. To all these men the university must give the means and the opportunities of obtaining the knowledge adapted to their several intellectual needs.

Spirit of University Training.

Of course, every person would be prepared to acknowledge that a university education includes more than even the most industrious and praiseworthy absorption of knowledge, and much of the influence of a university depends upon the spirit and the circumstances in which knowledge is given and received. There is an education of character as well as of mind, and the two can be achieved simultaneously by the due conduct of studies. Thoroughness must be the dominating quality in every study; difficulties which arise must be solved, not evaded; proofs must be sternly examined and only accepted if found valid and clearly comprehended; truth, and not merely comfortable or convenient doctrine, must be the object of search; and all must be done in a spirit that would scorn dishonesty or shuffling about the affairs of the mind as contemptuously

as one scorns dishonesty or shuffling about the property of one's neighbour.

Nor is it less important that the imagination should be stimulated. Some stimulus will come from every study, honestly and thoroughly pursued; according as it is greater or less, so is the greater or the smaller advantage to the student—not then alone, but throughout his life, as affecting his power, his influence, his usefulness. Above all, it is important to have what may be called the play of intellect between the teachers and the students, and, more particularly, in all liberty among the students themselves; it makes for force of character, for steadiness of character, for command over powers, for fairness, for soundness of judgment, for proper confidence in one's self, for proper consideration for others, for toleration, for knowledge of men, and for the seriousness of life. This phase of education is more important than mere instruction, and a university in which it is not secured provides but a maimed and stunted education. It stirs, it moves, it creates, the sentiment felt to the university; its operation has something of the air of spiritual romance, something also of elusive mystery. It cannot be secured by regulations or endowments; it is a product of the spirit of the place and the spirit of the time, difficult to establish as a custom, a treasure beyond value when once established as a tradition.

Each university in its own manner must evolve its own method of establishing this influence; the utmost that its formal regulations can achieve is the due provision for the intellectual needs of all classes of students.

Range of Instruction.

To discharge this duty, fraught with issues so grave to the good of the community, one necessity for the ideal university is that her courses of possible instruction should cover the whole field of human thought and intellectual activity, so that she can take her part in the diffusion and the extension of knowledge. She should possess such a collection of teachers that a student could obtain instruction in any department of knowledge, and could be trained in the use of any method by which knowledge is obtained. All sources of knowledge must be open to all students as they want them; all aids to learning must be provided. She must foster the liberal studies where "nothing accrues of consequence beyond the using"; she must foster the useful studies where the revenue to be produced is of essential consequence. In every art, in every science, in any study which is neither an art nor a science, the spirit of inquiry should be encouraged; and the only dogma permitted to the teacher should be his guiding advice based upon knowledge and experience.

To those who are acquainted with the working of actual universities, my claims may be deemed excessive. But it is to be remembered that I am dealing with an ideal university, and there is no doubt that, in this form of human activity as (I imagine) in all other forms, working practice will be derived from the too lofty ideal by the omission of some of its constituents. Moreover, the omissions may reflect the wishes, the preferences, even the prejudices, of the founders and the supporters; they may also be some index of the neediness of the university in actual work. Whatever their cause, they will tend to vary from one centre to another, and thus each working university will acquire its individual character, and monotony of character will be avoided.

Making this passing concession to the limitations that inevitably cramp the initial stages of great undertakings and sometimes shallow their whole course, let me return to my ideal university where all departments of knowledge are represented, and attempt some classification of these departments so as to give greater clearness and precision to some of its activities. They are set out in the order in which they arose naturally to me when considering them —no other significance, either of preference or importance, is implied in the order.

Position of Theological Studies.

As a preliminary let me deal with a matter which must be settled in the case of each university specifically and particularly—the attitude towards theology. The older among our foundations include its study within the curriculum; the tendency of most of our new foundations is to exclude its study. My ideal university is to make provision for every department of knowledge, and, as theology is undoubtedly a branch of knowledge, she must make provision for the teaching of theology. But in my university, thought is to be free from all fetters of official type, including those imposed by the churches, and the spirit of inquiry is everywhere to be encouraged. These conditions exclude all that part of theology which is expounded definitely on the basis of dogma, and, so far as I see, admit all else. Thus dogmatics, apologetics, pastoral theology, would be excluded; exegesis, ecclesiastical history, the characteristics and distribution of religions, and the history of religion, would be included. Provision would have to be made for the teaching of these latter subjects, and it is more than probable that each of the teachers would have some definite dogmatic position. But of the intrusion of dogmatic views into the exposition of the retained subjects I am no more afraid than I should be of the intrusion of party politics into the academic exposition of history or (what is to be stirred into passionate interest in England in the very near future) into the academic exposition of economics. Nor to my mind is there any arbitrary quality in the action which would include a portion of theology and leave the rest to be obtained, presumably in some theological school of the appropriate dogmatic hue. My ideal university is to include the whole field of human knowledge; but it is not to include everything based on human belief or beliefs, any more than it is to include everything based on human activity, and I do not require it to make provision for the whole training of a dogmatic theologian any more than to make provision for the whole training of (say) a surgeon or an engineer.

Branches of Knowledge, Subjective to Man.

Having now expounded this opinion as frankly as is consistent with the brevity imposed upon me by circumstances, I pass to a review of other activities of the university which usually do not give rise to contentious difficulties. As a beginning must be made somewhere, let us begin with man. We may regard him as engaged in the conduct of his own existence, possessed of mental faculties, directed by certain tastes, exercising mental activities, standing (either as an individual or as one of a group) in multifarious relations with other men; he is placed amid a universe, and there are the phenomena of that universe, living or inert, outside him. Each of these qualities, if they may be so styled, gives rise to a branch or to several branches of knowledge.

Our first quality of man as an existing being has regard to his conceptions of the general nature of knowledge and existence as such, and to the theory of his conduct of his own existence; the branches of knowledge related to those conceptions and that conduct are most simply described by the titles of metaphysics and of moral philosophy or ethics.

His next quality pictured him as possessed of mental faculties. The range of these faculties, their detailed activities, their modes and methods of working, to mention only some of their features, give rise to the branches of knowledge described by the titles of psychology and logic. In theory, there are close relations between logic and mathematics; in practice, particularly the older practice, mathematics as a subject has usually been derived from the study of nature.

Man then was indicated as directed by certain tastes; in this indication, it is mainly his æsthetic faculty that is contemplated. The branches of knowledge associated with the æsthetic element in man are conveniently summarised in the title of the fine arts, meaning thereby the arts of music, architecture, sculpture, and painting, alike in their industrial and their intellectual aspects.

When we contemplate the quality of man as connected with the exercise of his mental activities, not in the mode of the exercise but in its results, we are practically face to face with the intellectual creations of all individuals in the aggregate. The section of knowledge which thus arises is so vast that there is difficulty in finding a single title to describe it. Taking account of such limitations upon the range of this knowledge as are implied in the other activities of man which have been explicitly recited, I shall perhaps most simply describe it as literature.

When we contemplate the quality of man as standing in relations with other men, either as an individual with other individuals, or as a member of a community with other communities, or as a citizen of a State with other States, the branches of knowledge arising through these relations are languages, law, economics, and history.

Thus far, every branch of knowledge indicated has arisen through the consideration of qualities directly appertaining to the individual man, either to himself alone or in association with others. But his circumstances have to be considered. He is placed in a universe, and before there can be any real approximation to a fit understanding of man and his surroundings, the phenomena of the universe must be studied in their facts, their laws, their orders, their significance, their influence. These studies are vast and varied; they are concerned with all the knowable relations of nature, alike animate and inanimate, and they give rise to that immense and ever-increasing ordered body of knowledge, usually called science in general. It includes all the particular sciences, and these may be ranged broadly in the three classes of mathematical sciences, physical sciences, and biological sciences, the first two of which have closer relations with one another than (as yet) either with the third.

Ramification of Studies.

Provision has to be made for the adequate teaching of all these branches of knowledge, and it will be seen that my ideal university is growing at an alarmingly rapid rate. Yet the growth will have to be much greater, in respect even to these branches of knowledge, than the statement can outline, exacting as it seems. Branches of study have been indicated as originating mainly in some one source or other, but any study, once definitely introduced into an ordered scheme of knowledge, may develop into issues vastly wider than its initial purpose. Examples occur at every turn. Languages arose in my enumeration through the relations between man and man; presumably, therefore, they arose for their use in oral communication. But they can be studied for other than utilitarian purposes. They may be studied organically, that is, for their accidence, their syntax, the sources of their words, the analogies and the differences in their methods, their growth and their mutations, their influence upon one another; these, and similar aspects of languages, constitute the science of philology, and provision will have to be made for its teaching. Further, I would make the mild remark that languages, ancient and modern, are the vehicle of literature in the widest meaning that can be given to the word, and a mode of teaching them, which is neither utilitarian (in my sense) nor philological, will be required for appreciation of the best treasures of thought, for comprehension of the records of development of nations, for intelligent understanding of the civilisations of the world.

As for languages, so for history, another of the subjects that in my enumeration arose through the relations between man and man. It may begin in our scheme as the record of the doings of particular peoples; it must develop into the history of mankind to which that of particular peoples is ancillary. The history made up of acts is not more important, rather it is less important, than the history of movements and the development of political thought. Account must also be taken of the fine arts, moral philosophy, religious thought, scientific thought, in that continuous succession which also is their history. For all these, and for the corresponding amplifications of other branches of knowledge introduced initially in the simplest of elementary demands, provision must be made in the university.

Other Branches of Knowledge.

When all this is recognised, and when all the demands thus made are acknowledged and met, then it might be imagined that the necessary provision of the university is complete and that she is fully equipped to discharge all her duties. Far from this being her happy reality, she must afford opportunities for another group of classes of knowledge of an entirely different kind. In the gradual elaboration of the scheme, many useful branches of knowledge have been established; yet in their inception they have been established rather as pure knowledge, and they do not attain their full significance until they have been so organised that the amplest utilitarian tax has been levied on their riches. There thus must be (to use the ancient word) a faculty of theology, a faculty of law, a faculty of medicine and surgery; though just as not all theology can be taught in the one faculty, for dogmatics have been excluded, so neither all the practice of law nor all the clinical elements of medicine and surgery can be taught in their respective faculties in the university.

Nor is this all. These practical organisations have been selected as being subjective to man, but they are not complete even within that categorical limit. Growing academic thought has discovered that other organisations of knowledge can fitly be framed; Birmingham now possesses a department of commerce, Cambridge has just established a new curriculum in economics, and not in one university alone has provision been made to meet a growing sense of the need for a department in the history, the theory, and the art, of education itself.

The tale of demands is not yet full. Only those branches of useful knowledge have thus far in the scheme been selected for utilitarian organisation which are most closely associated with man's health and man's human relations. There still remain those other branches of useful knowledge which, fitly organised and selected, will train men to wield the forces of nature for the advantage of the community. Perhaps the most conspicuous example of such a group of branches of knowledge is provided by the school of engineering which certainly must exist in our ideal university, to include instruction in electrical engineering, in mechanical engineering, and in naval engineering; and other examples, following the wisdom of recent establishments, will be given by a school of agriculture, a school of tropical diseases, and departments of particular industries depending largely upon the locality of the university. It lies with the future gradually to work out the balance between practice and training, and to settle the proportion between experiment and experience, in the equipment for professions of the newer order as has been done for the professions of medicine and surgery. And let me add two warnings. While the earlier stages in any such process continue, there is more than a probability that old ideas as to what constitutes a university education will receive rather rude shocks, and may occasionally be staggered. I would, very respectfully, urge a caution against the exclusion of any subject of new technical knowledge from the university, either actual or ideal, if only because no man can foretell its possible tribute to even abstract theories; I would suggest that its prudent reception in a not too unsympathetic spirit is a preferable mode of exercising the caution of academic wisdom. On the other side, the fiery and occasionally arrogant advocates of devotion to the newest learning would do well to temper their vehemence with intellectual charity. Before they came upon the scene, thought had propounded problems which their sciences cannot touch; after they shall have left it, thought will continue to propound problems equally unamenable to their sciences.

Extension of Knowledge: Research.

Hitherto, I have spoken of the university as a treasury of all ascertained knowledge which is to be given without stint to all qualified students coming for its wealth, and those who distribute this wealth are the professors and other teachers. But that duty, no matter how excellently discharged, is not the sole duty of these officers in respect of knowledge; if it were, the university would only be a rather glorified secondary school. It is true that we have not supposed our ranges of study to be confined to antique knowledge which is crystallised; on the contrary, all knowledge is to find its home in our university and, at the fitting stage, the students will be brought into contact with living knowledge, growing, increasing, and in its very vitality proving the greatest stimulus to the ardent mind. You would not be content that the estimates of literature should only be those of some bygone generation. The last word in judgment of painters and painting had not been uttered when Ruskin finished his great book. Almost from day to day, a chapter in the history of civilisation anterior to the Greeks is being opened up by the discoveries in Crete. Not all the problems of history are solved, and their solution will add to the knowledge of the past, perhaps to the

comprehension of the present. After the past week, you will not need to be told in detail how, in every direction, the sciences, abstract, concrete, practical, are advancing by leaps and bounds. Progress is the condition, it is the essence, of living knowledge; it should be the very breath of life of the university.

How is this progress to be secured, and the knowledge of it made available? It is manifestly the duty of the professors to assimilate new facts as they come, and to submit them to those critical refining and concentrating processes which make the surviving product some contribution to truth. But is there to be nothing else on the part of the professors? Is it to be "all take and no give"? all absorption and no production? Are they to profit by taking toll of all the thought of the world, and to contribute nothing for toll in return? I hold it to be the highest duty of a teaching professor that, up to the limits of his powers, he should strive to contribute to the increase of knowledge and the advancement of truth.

Now I know that all professorial spirit is not the same spirit. There is a spirit which devotes itself to administration; its works deserve grateful acknowledgment, and they are undoubtedly indued with the exercise of power, so dear to many souls. There is a spirit which devotes itself to the humanising and social influences that should be a feature in the life of a university; its labours are blest in a quickened vitality that affects the whole community. But the spirit of research must also be there; not alone the quest of facts, but the quest of truth, which is higher than facts; not alone the love of novel thought, but the love of wisdom, which is the crown of thought. You cannot secure it by regulations; a professor will devote himself to research in proportion as he likes it, not because it is an expected duty. You cannot exact it from every professor; but there must be a substantial amount of research produced by the aggregate of professors, or their corporation will fail to contribute its share to the advancement of learning. Moreover, in the absence of research, the university will fail in other respects, for it will be unable to exercise the profoundest of all influences upon the most earnest of its students whose later duty it will be to carry on the torch of learning—I mean the influence of stimulus and inspiration.

Will you let me be reminiscent for a few moments? When I was an undergraduate at Cambridge studying mathematics in all the earnest and kindly rivalry that is frankly and easily possible among young men who are friends, there was, among the professors, a group of four men of supreme eminence, Stokes, Cayley, Adams, and Maxwell. We were not (or we thought we were not) sufficiently qualified by our attainments to attend their lectures in our earliest days; but our teachers could tell us of their powers, their genius, something of what they had done or were doing, and we knew that they stood among the great men of the world. Do you think it was a little thing to young men at the opening of life that they belonged to a university which possessed such illustrious pioneers of learning? I can tell you that, though the young men then knew themselves hardly worthy of entrance even into the court of the Gentiles in the temple of new knowledge, the mere presence of the great men stimulated them and inspired them along the paths which led to the temple. I have spoken of one group of professors, great men in the domain of knowledge that was our special pursuit; I would mention another group of professors possessed by Cambridge at that time, equally great in another domain, that of theology. They were Lightfoot, Westcott, Hort. To theological students I suppose that they stood for as much as did the mathematical group to us; but even to those of us who were not theological students their achievements made the university a more stimulating home of study, though we knew nothing in detail of their work. All these men are dead, the oldest of them all only a few months ago; their bodies are buried in peace, but their names live for evermore, a treasured inheritance and the proud possession of the university of which during their lives they were an ornament, a glory, and an inspiration.

This deviation into personal reminiscence is undoubtedly an interruption of my main line of argument. Yet these particular examples of fact may do more than any ordered sequence of reasons could do for the establishment of my contention that a healthy university must contribute not merely to the diffusion of knowledge, but also to the advancement of learning.

CONCLUDING REMARKS.

I have spoken at length of some of the aspects of universities, and have incidentally alluded to others, and some have been omitted entirely. It is time, however, that my remarks should draw to a close, and so I leave the subject with you at this stage. Earlier in the evening I confessed that the receipt of the charters of the Universities of Manchester and of Liverpool suggested my subject. But the real reason for its selection was a desire on my part to do something by way of concentrating your thoughts, and, through you, the thoughts of others, upon the significance of university education, for I believe that a vigorous university can exercise a most beneficent influence upon the life of a nation. It certainly can play its part in so training men that they can contribute to the commercial success and the material welfare of the people among whom it is placed. But it can do more. The greatness of a people is not to be measured solely or even mainly by its commercial success, or the extent of its empire, or the vigour of its fighting powers. Thought has its part in life, no less than action; frequently it dominates action; often it is more potent than action in its influence upon the course of civilisation. In estimating the position of a nation in the scale of the world, not a little weight ultimately is attached to its devotion to learning. The spread of learning makes for the clearer understanding of the nations by one another, and consequently assists towards developing feelings of comity and invoking the spirit of peace. Universities can do much as agents in the achievement of these aims as of others that are more utilitarian. They give to their people a wider range of knowledge and a higher standard of culture, and they can organise the genius and the ability of a nation so as to feed the living springs of action and enable it to make no unworthy contribution to the growing thought of the world.

ASTRONOMY AND METEOROLOGY AT THE BRITISH ASSOCIATION.

THE proceedings of the department of Section A which was devoted to astronomy and meteorology were conspicuous this year on account of the meeting of the International Meteorological Committee, which was held during the Association week, and brought to Southport not only representative meteorologists from the United States, France, Germany, Austria, Russia, Sweden, Norway, Denmark, Holland, and the Azores, but also a very notable gathering of British meteorologists. The muster at the meteorological breakfast, which was organised by Dr. H. R. Mill, was not less than sixty-two.

International Committee Meetings.

The meetings of the International Committee, under the presidency of Prof. Mascart, and of the Subcommittee for International Telegraphy, under the presidency of Prof. Pernter, were so arranged that the members could attend the meetings of the department. Several of them made communications to the section and took part in the discussions. The variety of language added to the interest of the proceedings, which were in gratifying contrast with the rather depressing occasions represented by the meteorology days as they used to be before the formation of a special subsection for cosmical physics.

Before going on to the work of the subsection, a word or two may be said about the work of the International Committees. First, for the subcommittee on weather telegraphy: its duty is to consider all matters which concern the efficiency of the arrangements for daily weather maps. In Europe these arrangements are of the most complicated character, and require the cooperation not only of a number of independent meteorological services, but also of an equal number of independent telegraphic services bringing messages, not as a rule from the centres of business, but from the most remote and exposed positions on the European coasts to the various central offices. The relations between

the several services are partly by way of exchange and partly by way of payment for services rendered, and complication is inevitable.

Considering the difficulties to be overcome, and the divergent interests of the different offices, the results already achieved, as represented in the weather maps of Europe, are a remarkable witness to the spirit and capacity with which the predecessors of the present committee have approached the subject. There are still some questions outstanding, for which a solution is obviously desirable, connected with the hours of observation and the time occupied in the transmission of the despatches. But questions of the observations and their transmission are so mixed up that they are as much matters for the telegraphic services as for the meteorological offices. Accordingly, the tendency of the committee, after prolonged consideration of many details, was towards a conference with the International Telegraphic Convention, and the work was devoted to formulating the questions which might be profitably raised in such a conference.

The International Committee itself is somewhat informal in its proceedings. It begins formally enough by recording changes in the personnel, which may have been already arranged by correspondence, and receiving reports from its Subcommittees. On this occasion these included, besides the report of the Telegraphic Subcommittee already mentioned, an important and final report from the Committee on cloud observations, the results of which were subsequently given to the Association by Prof. Hildebrandsson, and an account of the work of the Aëronautical Committee, of which results have been already published by the German Government, and which were also referred to subsequently in the proceedings of the section. To this was added, as a supplement, an account by M. Teisserenc de Bort of the Franco-Scandinavian aëronautical station in Jutland, established by him in 1902 with the cooperation of the meteorological authorities of Denmark, Sweden, and Norway. Other work in connection with the exploration of the upper air was mentioned.

The committee then went on to consider various proposals for the extension or improvement of observations, referred to the committee or made by individual members, among which were to be found proposals for the organisation of observations of atmospheric electricity referred by the Academy of Science of Saxony, the institution of regular observations of solar radiation, and various other matters of a more or less technical character; an account of these details will be given in the official report of the proceedings. An English translation of the report will be published as usual by the Meteorological Council.

Two important resolutions, one appointing a subcommittee to organise a committee for dealing with simultaneous solar and terrestrial changes, and the other directing the attention of the British Association to the inconveniences of the present practice of having different systems of units of measurement for meteorological observations, are referred to later on.

At the close of the meeting of the committee, at which a cordial vote of thanks was passed to the Mayor and Corporation of Southport for the use of the committee room of the Town Hall for the meetings, the following future international assemblies were announced:—In 1904, a meeting of the subcommittee for terrestrial magnetism at Cambridge, and a meeting of the aëronautical subcommittee at St. Petersburg; in 1905 a conference of directors of meteorological offices and observatories at Innsbrück.

Meetings of the Department for Astronomy and Meteorology.

Meetings of the subsection of the Association devoted to astronomy and meteorology were held on Friday, September 11, and the following Monday, Tuesday, and Wednesday. During part of the session of Monday and on Tuesday meetings of the remainder of the section were held, simultaneously with those of the department, for the discussion of papers on mathematics and physics.

The proceedings on September 11 commenced with the chairman's address, which has already been printed in these columns. Arising out of a vote of thanks proposed by Prof. Schuster, there came what may prove to be an important suggestion, that the time has now arrived when meteorologists of all countries should adopt a uniform system for the measurements of pressure and temperature. Those quantities have certainly been measured long enough for men of science to be able to agree as to what is the most scientific and the most practical way of expressing them. The result of Prof. Schuster's suggestion appeared first as a communication from the International Committee, and subsequently as a resolution upon the subject by the General Committee of the Association. The address was followed by a discussion of simultaneous solar and terrestrial changes, introduced by the president of the Association, Sir Norman Lockyer, in a paper which gave a short account of the history of the various measurements that have been made bearing upon the subject. In association with this paper, a paper by Dr. Buchan on the distribution of rainfall in Scotland in relation to the sun-spot period was taken, and a general discussion followed, in which Dr. Hellmann, of Berlin, referred to the work done in Germany upon the subject, and Father Cortie, of Stonyhurst, opposed the view that the connection between solar prominences and terrestrial phenomena is directly one of cause and effect. When the subject was subsequently considered by the International Meteorological Committee, a subcommittee was appointed to carry on its further development. The original members named are Mr. Shaw, Prof. Pernter, Sir Norman Lockyer, Prof. Langley, and M. Angot. Upon these now devolves the duty of organising the subcommittee for the furtherance of the object in view. After the discussion, M. Teisserenc de Bort read a paper in French, "Sur les dépressions barometriques," in which he traced in detail the vertical structure of barometric depressions as determined by observations of the upper air. In the afternoon Messrs. Grossmann and Lomas exhibited some interesting pictures illustrating the origin and forms of hoar frost obtained in a refrigerating chamber.

On Monday, September 14, the proceedings opened with a paper in German by Prof. Pernter, of the Austrian Meteorological Office, upon the use of the hair hygrometer in place of the psychrometer for purposes of ordinary observations of humidity. The contention of the paper was that both instruments required empirical graduation, and that if the same trouble were devoted to the empirical graduation and management of the hair hygrometer as is now required for the psychrometer, the results would be more satisfactory. Prof. Pernter exhibited a specimen of the instrument in which no pulley was used, and one important cause of objection to the hair hygrometer was thus avoided. He also exhibited a very interesting photograph from the Sonnblick of a portion of a halo which had been predicted on theoretical grounds, but had never been observed before, as it is formed below the horizon line. Attention was next turned to astronomy by a paper of Prof. Turner's on the question, "Was the new star in Gemini shining previously as a very faint star?" On photographs of the region taken by Dr. Max Wolf at Heidelberg and by Mr. Parkhurst at Yerkes, a faint star is shown very near the place of the Nova; but the evidence was on the whole against identity, and this conclusion was confirmed by a letter from Prof. Barnard, received on the morning of the meeting, announcing that he had observed the faint star shining beside the Nova. The subsection then reverted to meteorology, and listened to a very important paper by Prof. Hildebrandsson, of Upsala, upon the results of the international cloud observations and their effect upon the general theory of the circulation of the atmosphere. Prof. Hildebrandsson first exhibited a reproduction of a drawing illustrating James Thomson's theory of the general circulation, which is practically similar to the scheme of general circulation adopted by Ferrel. He then showed a series of diagrams representing the motion of the upper atmosphere as determined by the motions of cirrus clouds deduced from cloud observations in all parts of the world. In some cases, also, the motion of the lower clouds was given. The general system of circulation thus established was shown to differ in most important particulars from the calculated circulation of Thomson and Ferrel. In the discussion an interesting point was raised by Prof. Hergesell as to the extent to which the motion of air could be inferred from the motion of clouds, clouds only being formed in certain states of the atmosphere; but the question was not solved.

The subject of kite observations and the general investigation of the upper atmosphere was then taken up. It was introduced by Mr. Dines, who gave an account of the work of the kite committee of the Association and of the difficulties met with in carrying out the continuation of the observations in the summer of this year off the west coast of Scotland. Dr. A. L. Rotch followed with an account of the kite observations at Blue Hill in the years 1900–2, and Prof. Hergesell added an account, for the most part in German, of the work of the International Aëronautical Committee. He concluded in English with an eloquent appeal to the science of this country to take a part in this important investigation. The three papers mentioned were followed by a general discussion, which had not concluded when the morning sitting of the section was adjourned. It was accordingly postponed until the following day, and then continued by Profs. Schuster, Turner, and M. Teisserenc de Bort. The matter was subsequently brought before the committee of Section A, and at their instance the General Committee at their final meeting adopted a resolution urging the council to take steps to secure the means of joining this international enterprise. The papers in the afternoon were one on photographs of the Orion nebula, by Mr. W. E. Wilson, showing what could be done by screening to bring out in a positive detail of the central overexposed regions of the negative, while preserving the faint extensions; on the spectra of lightning, by Dr. W. J. S. Lockyer, which formed a suitable companion to the author's fine collection of photographs of lightning in the meteorological exhibition, and which was further elucidated by a photographic spectrum of lightning from Yerkes Observatory; and also a paper by Mr. D. Burns, attributing some of the unexplained phenomena accompanying volcanic eruptions in the West Indies to electrical action.

On Tuesday, September 15, Prof. Milne, whose ill-health during the meeting of the Association unfortunately prevented his taking much part in the proceedings, read the report of the seismological committee, and gave an account of his conclusions on the present state and properties of the interior of the earth. That was followed by a number of astronomical papers. Prof. Hale sent from the Yerkes Observatory a series of very fine photographs made with the new Rumford spectro-heliograph mounted on the 40-inch refractor. By setting the slit in different parts of the K line he is able to photograph the distribution of calcium vapour at successive heights above the photosphere, and to show how the calcium "flocculi" expand as they rise and spread out over the spots. He announced also the existence of *dark* hydrogen flocculi and of occasional dark calcium flocculi. Prof. Schuster contributed a very important paper on radiation from a foggy atmosphere, finding in the "scattering" of light by molecules an explanation of the fact that a star may show the hydrogen series partly bright and partly dark. A paper by Prof. Sampson announced some of the results of the eclipse observations of Jupiter's satellites upon which he is now engaged; and one by Father Cortie on solar prominences and terrestrial magnetism went to show that no direct relation in detail could be traced between individual prominence outbursts on the sun and terrestrial magnetic storms. The conclusion was that both depend on some deep-seated common cause, and not directly one upon the other. There followed a paper by Dr. Paulsen, of Copenhagen, in which the spectrum of nitrogen was compared with the spectrum of the aurora obtained by long exposure in the Arctic night of Iceland. Dr. Buchan gave an account of the results of an investigation of the variation of temperature in the water of the Levant, which regularly gains temperature during one part of the day and loses it all again within the twenty-four hours. This gain and loss Dr Buchan attributed to the effect of absorption and radiation. The decision between that hypothesis and the alternative suggested by Mr. J. Aitken, that it might be accounted for by convection, was left as an attractive subject for further consideration.

The work of the day concluded with some magnetic papers, Prof. Schuster reading for Dr. Bauer, first an account of the progress of the magnetic survey of the United States, and secondly an attempt to compute the secular variation of the earth's total magnetic energy. The report of the committee of the Falmouth Observatory, to which the Association is giving a liberal subsidy, in order to maintain a self-recording station free from the electrical interference which has destroyed the usefulness of the Kew observations, until a new national magnetic observatory is established, was merely formal.

The subsection continued its labours up to the end of the available time of the Association. On Wednesday, Dr. W. J. S. Lockyer read a paper on the relation between prominences, sun-spots, and coronæ. Dr. Buchan produced the twenty-first report of the committee on Ben Nevis Observatory, which concluded with a summary of the results as bearing on forecasting. Prof. Callendar gave an account of the electrical self-recording instruments designed by himself, and pointed out their advantages over those in general use. There are so many points in connection with the practical use of self-recording instruments to which it is desirable that attention should be directed that it is to be regretted that the limited time of the section did not permit more extended discussion of the general question. Dr. A. L. Rotch gave an account of the results of his experiments at Blue Hill upon the effect of meteorological conditions upon the audibility of sounds between a high-level and low-level station. The results were of a negative character on the whole; no specific effect could be attributed to differences of meteorological condition. The business concluded with a paper by Dr. Mill on some rainfall problems, in which he discussed some practical difficulties arising in the construction of accurate rainfall maps. The usual vote of thanks concluded the proceedings.

Exhibition of Objects of Interest in Meteorology, Terrestrial Magnetism, &c.

In connection with the meeting of the International Committee, an exhibition of objects of interest in meteorology and allied subjects, terrestrial magnetism, solar physics, seismology, &c., was organised. The preliminary arrangements were made by a committee which met at the Meteorological Office, and consisted of representatives of the Meteorological Council, the Royal Meteorological Society, the Scottish Meteorological Society, the president of the Association, the Astronomer Royal, the director of the National Physical Laboratory, and a number of others interested in the subjects represented. The result was the collection of a large number of very interesting exhibits from the following exhibitors:—

The Admiralty, Hydrographic Department, magnetic apparatus; the Astronomer Royal, historical instruments, magnetic and meteorological records; the Meteorological Council, books, maps, diagrams and automatic records; the National Physical Laboratory, Kew Observatory, McLeod's sunshine recorder, cloud apparatus and photographs, records and diagrams illustrating meteorology, magnetism and seismology; Prof. A. A. Rambaut, Radcliffe Observatory, barograms showing disturbances due to volcanic eruptions, and diagrams of the results of earth temperature measurements; the Royal Meteorological Society, Glaisher's balloon apparatus and other objects of historic interest; the Scottish Meteorological Society, photographs of Ben Nevis and special rainfall maps; Sir Norman Lockyer, F.R.S., Solar Physics Observatory, diagrams of solar phenomena and of the secular variation of pressure in different parts of the earth; M. Teisserenc de Bort, records of unmanned balloon ascents etched on metal sheets; Mr. John Aitken, F.R.S., dust counters and koniscope, with a map exhibiting some results obtained, and an apparatus illustrating certain phenomena of cyclonic storms; Mr. J. Baxendell, new self-recording apparatus for temperature and for wind direction combined with wind force, diagrams and records from the Fernley Observatory, Southport; Mr. F. F. Blackman, apparatus for demonstrating and measuring the evaporation of water from the leaves of growing plants; Mr. F. J. Brodie, diagram of gales; Dr. Buchan, F.R.S., meteorological atlas; the Cambridge Scientific Instrument Company, Callendar recorders for temperature and sunshine, and Blakesley's portable barometer; Captain E. W. Creak, R.N., C.B., F.R.S., magnetic charts; Mr. W. H. Dines, tornado cloud apparatus and kite records; Mr. F. L. Halliwell, new self-recording rain gauges; Mr. F. W. Harmer, diagrams of suggested isobaric distributions in the Glacial

epoch; Mr. J. J. Hicks, various apparatus, including a standard thermometer without any error shown in the Kew table of corrections between 32° and 212°; Dr. W. J. S. Lockyer, photographs of lightning and of the spectrum of lightning; Dr. H. R. Mill, rainfall maps; Mr. R. W. Munro, new pressure plate anemometer by Dines; Messrs. Newton and Co., altimeter; Prof. J. M. Pernter, new self-registering electrometer and anemometer, also hair hygrometer and photometeorometer; Mr. A. Lawrence Rotch, instrument for determining the velocity of wind at sea, kite investigation exhibits, photographs of high-level stations and of the figures of the winds from the Horologium at Athens; Dr. R. H. Scott, F.R.S., Russian climatological atlas; Dr. W. N. Shaw, F.R.S., Galton's "Meteorographica" and other historical exhibits, lantern slides, apparatus and diagrams illustrating the motion of air in circular storms, and apparatus illustrating the circumstances of the formation of cloud in free air; Prof. F. T. Trouton, F.R.S., gravimetric recording hygrometer, and an electrical dew-point hygrometer; Mr. C. T. R. Wilson, F.R.S., experiments on ionisation; Commander Wilson-Barker, R.N.R., cloud studies—photographs; Dr. W. Mansergh Varley, for Mr. P. Y. Alexander, *ballons sondes* records; Mr. A. Lander, new sunshine recorder, anemometer, and thermograph.

It is difficult to particularise in a short notice the exhibits which deserved or those which received the greatest attention. Not the least interesting was the one representative of the connection of meteorology with botany, exhibited by Mr. Blackman, an apparatus which showed the rate at which water evaporated from the leaves of the branch of a tree. From the point of view of meteorology, probably the most important exhibits were the comparatively inconspicuous sheets of metal or paper on which were recorded the results of balloon or kite ascents by M. Teisserenc de Bort, Mr. Rotch, Mr. Dines, and Dr. Varley, one of the records exhibited by the last-named gentleman extending to the height of 70,000 feet. The opportunity of seeing the working of Mr. Aitken's dust counters, Mr. Wilson's experiments on the effect of the electric field upon condensation of water particles, with other noteworthy experiments, the collection of weather maps of all countries, of magnetic apparatus old and new, and of the diagrams bringing together the results of observations from all parts of the world, will probably remain among the most satisfactory recollections of the meeting in Southport. The local exhibits by Mr. Baxendell, of the remarkably well equipped Fernley Observatory, and his assistant, Mr. Halliwell, were admirable examples of the best kind of progress in meteorological instrument making, and a word ought to be said for Mr. Lander, of Canterbury, who exhibited some self-recording instruments of his own construction, among others a sunshine recorder which keeps the record of sunshine for a month on a half-plate sheet of photographic paper.

An interesting exhibit, which could not be confined to the four walls of a building, was a specimen of the mortars used in southern Europe for bombarding the clouds, as described in the columns of NATURE, vol. lxiv. p. 159. The apparatus was brought and exhibited by Prof. Pernter, being placed at his disposal by the makers for the demonstration of the remarkable vortex rings which are produced by the discharge of the mortar, which is provided with a large funnel-shaped attachment. The discharges were directed horizontally, and though the rings did not carry smoke enough, as a rule, to be easily followed by eye, some of them showed their structure and others could be heard hurtling along the promenade for a considerable distance.

Finally, mention should be made of the arrangement carried out in connection with the exhibition by the Meteorological Council for the preparation at Southport of a weather chart of north-west Europe with remarks and forecasts in the same manner as those of the daily weather report of the Meteorological Office. For this purpose the reports of observations received in London were sent on by telegraph to Southport, and there charted and dealt with; the evening information of which account has always to be taken in preparing morning forecasts was sent by post and charted in readiness for the arrival of the telegrams.

A special feature of the Southport edition was found in maps of the distribution of maximum and minimum temperatures, sunshine and rainfall for the previous twenty-four hours, which replaced the three supplementary maps of the daily weather report.

The primary object of the arrangement was to enable the members of the British Association to examine for themselves the method adopted by the Meteorological Council for dealing with daily weather information, but it was also an experiment by which one can estimate the conditions necessary for carrying out a system of distributing telegraphic information to local centres to be there dealt with independently of, but in association with, a central office. At present in this country there is only one centre for the preparation of reports and forecasts, although the local conditions of the three kingdoms are very complex. The trial of the preparation of independent reports from the same data is therefore of more than temporary interest.

In the chapter of accidents it came about that the Southport week exhibited remarkably typical examples of British weather, including the rapidly travelling circular storm of September 10, with accompanying heavy rainfall, and the persistent anti-cyclone of the following week, with its autumnal mornings and atmospheric effects. Unfortunately all the types were cold, and the visitors from over sea were more impressed with the meteorological interest of the week's weather than with its geniality. The series of maps remains a very interesting group of specimens for weather study.

W. N. SHAW.

ARCHÆOLOGY OF THE COAST OF NORTH-WEST FLORIDA.[1]

MR. CLARENCE B. MOORE has concluded his thorough archæological survey of the coast-line of north-west Florida. Although this district had not previously been investigated, many mounds had been opened by treasure seekers and curiosity hunters, and thus valuable data have been lost to the students of American archæology. This irresponsible exploitation of mounds for spoil has caused great loss to science in America, but the loss in the Old World has been infinitely greater, and too often this ignorant digging has been carried on under the auspices of "learned" institutions.

By far the greater portion of Mr. Moore's finds consists of pottery which has been added to the noble collection that this enthusiastic archæologist has given to the museum of the Academy of Natural Sciences at Philadelphia. Indeed, there are in the various museums of the United States enormous collections of pre-Columbian and more recent pottery, comparatively little of which has been studied or published. It is to be hoped that ere long one of our American colleagues will give us a monograph on American ceramics as a whole; a work on this subject is much needed at the present day, and it could not fail to be of very great interest.

There is so much variety in the vessels so numerously and beautifully figured by Mr. Moore that it is difficult to give an idea of the pottery of the district investigated. Many vessels are composed of several cups or receptacles, most are of irregular form and are often provided with animals' heads, a few are perforated, and some are in the form of human effigies; a unique vessel has the form of an inverted truncated pyramid, on one side of which a human figure peering over the edge is modelled in relief. The majority of the vessels are decorated in various ways, usually either by incised lines or by devices or patterns in low relief, many of which look as if they had been produced with a stamp; one simple cylindrical vessel is ornamented with an incised design representing two human hands, but most of the designs and patterns have no obvious significance.

A good many human crania have been found, and these exhibit great antero-posterior flattening, while in some a concave depression gives evidence of early constriction by a band. Captain Bernard Romans, who was familiar with

[1] "Certain Aboriginal Remains of the North-west Florida Coast." Part ii. By Clarence B. Moore. (*Journal* of the Academy of Natural Sciences of Philadelphia, 2nd series, vol. xii., part ii., 1902.)

this part of Florida, writing in the latter part of the eighteenth century, tells us that in his time the Choctaws bound bags of sand to the heads of male children; but skulls of females exhibit the same artificial deformation.

The region investigated by Mr. Moore shows in an interesting manner the influence of other districts. The pottery of north-west Florida is, on the whole, much superior to that of the peninsula, and the author is inclined to believe that the best ware found its way into the latter region through barter, and the comparative rarity of the imported ware may account for the infrequent occurrence of earthenware vessels in the burial mounds of the coast of the peninsula.

In the first part of the report (*Journal* Acad. Nat. Sci., Phila., xi., 1901, p. 439) Mr. Moore noted a mortuary custom prevailing in peninsular Florida, which consisted of knocking a hole in the base of a vessel, presumably to "kill" the pot, that its soul might accompany that of the dead man. The flimsy and "freak" pottery sometimes found in the peninsula, and numerously in the north-west, was made expressly for interment with the dead, and in the base of each vessel a hole had been made previous to the baking of the clay. A new feature in "freak" ware was encountered about St. Andrew's Bay; these vessels

FIG. 1.—Perforated mortuary vessel from St. Andrew's Bay, Florida.

were life-forms, usually, but differed from other life-forms of the same district in that they were inferior to them as to ware and workmanship, and that they had various perforations, made previous to baking, in the body of the vessel as well as the customary one in the base.

Mr. Moore also obtained evidence which suggests that the flesh was removed from the bones of the corpses and burnt; the mass of carbonaceous matter was always found on the eastern side of the mounds. Urn burial was largely in vogue in Alabama and Georgia; it extended into Florida, but practically is not met with further east than St. Andrew's. Inhumation was almost universally practised in Florida; true cremation has not been met with in the peninsula, but it was occasionally practised on the mainland, or north-western portion. These observations confirm the statement of Cabeça de Vaca, who spent some years among the aborigines of the north-west Florida coast; he says that persons there in general were buried, but that doctors were cremated. Mr. Moore is to be warmly congratulated on having brought his labours to so successful a termination, and the Philadelphia Academy of Natural Sciences is fortunate in possessing so liberal a benefactor. It is to be hoped that these instructive collections will be suitably and worthily displayed.

A. C. H.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—In accordance with general expectation, Dr. J. N. Langley, F.R.S., has been elected professor of physiology in succession to Sir Michael Foster, K.C.B., F.R.S.

Dr. A. Hill has been reappointed university lecturer in advanced human anatomy. Dr. A. C. Ingle has been appointed university lecturer in midwifery. Mr. J. de Gruchy Gaudin has been appointed a governor of the University College of North Wales, Bangor.

An Allen studentship of the value of 250*l.* for one year, for research in any branch of study connected with medicine, mathematics, physics and chemistry, biology and geology, or moral science, will be vacant next term. Candidates must be graduates of the university and not more than twenty-eight years of age.

Mr. Newall will lecture next week on Hale's recent investigations of the sun's surface, with illustrations obtained from Prof. Hale, of the Yerkes Observatory.

The State Medicine Syndicate reports that during the present year eighty-eight candidates have presented themselves for examination in sanitary science. Forty-one were successful in obtaining the university diploma in public health.

Sir Walter Gilbey has been appointed an additional member of the board of agricultural studies.

A syndicate is to be appointed "to consider what changes, if any, are desirable in the studies, teaching, and examinations of the university, to confer with any persons or bodies, and to submit a report or reports to the Senate before the end of the Easter term, 1904." The members proposed are the Vice-Chancellor, Sir R. C. Jebb, Dr. A. W. Ward, Mr. Austen Leigh, Mr. W. Chawner, Dr. D. MacAlister, Prof. A. R. Forsyth, Dr. J. N. Keynes, Prof. J. J. Thomson, Mr. R. S. Parry, Mr. J. W. Cartmell, Mr. W. Durnford, and Mr. W. Bateson. It is understood that one of the first questions to be considered will be that of "compulsory Greek."

THE War Office has sanctioned the provision of a guard of honour on the occasion of the visit of Lord Kelvin to Cardiff to receive an honorary degree from the University of Wales.

THE Commissioners for the Exhibition of 1851 have offered a nomination for an 1851 science exhibition to the South African College, Cape Town, for 1904, and hope to repeat the offer in 1906 and subsequent alternate years.

DR. C. S. MYERS has been elected to the lectureship on experimental psychology at King's College, London, rendered vacant by the resignation of Dr. W. G. Smith, who has been appointed to a similar post at the University of Liverpool.

THE Prince and Princess of Wales will visit the Battersea Polytechnic on Wednesday, February 24, for the annual distribution of prizes to evening students and the formal opening of a new block of buildings in the women's department.

AT the half-yearly meeting of the governors of the University College of North Wales, held on October 28, the chairman stated that in all probability 5000*l.* would be received from the trustees of the late Dr. Evan Thomas, and that it had been decided to allot that sum to the new building fund.

A NEW Royal college at Posen was opened on November 4 by Herr Studt, the German Minister of Education. Herr Studt, in declaring the building open, referred to the Emperor's deep interest in the education of eastern Germany, to which the new college largely owed its existence. The new foundation was to be a university in the true sense, he continued, for it would serve the needs of all the population, including even that section of the Poles which still held aloof.

THE civic inauguration of the University of Liverpool took place on November 7 in St. George's Hall, Liverpool. The Lord Mayor of Liverpool presented the charter of the university to the Chancellor, remarking that no one had

done more than Lord Derby to further the movement for the establishment of the university. Lord Derby, on accepting the charter, said they could now hope that the new university would become the centre of learning of a great, active, industrious, and well-employed population. Sir Oliver Lodge, who took part in the proceedings, remarked in the course of a speech that something substantial must be done for higher education. Hitherto the country had been content to leave this to private munificence, and private munificence had done well, but unaided it was unequal to the burden. He trusted it was not impolitic for him to say, without regard to party questions, that he regretted that a registration duty which was doing no harm, and was hardly a subject of controversy, should have been flippantly thrown away when no longer needed for the Exchequer, instead of being ear-marked for higher education. That amount would have been sufficient to put the education of the country on a sound, thorough, and, indeed, magnificent basis, and would have enabled them to hold up their heads once more amongst the educated nations of the world. Referring to local support, Sir Oliver Lodge expressed the hope that whatever aid was given by the municipality, they would not abolish fees. It was only just, right, and natural that those who specially utilised the institution should make special contributions to it, but by all means they ought to provide scholarships for unmoneyed ability. His advice was that the scholarships should be provided as little as possible on the basis of competitive examination and as much as possible on the basis of nomination from schools and institutions to which the scholarships were assigned.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 18.—"On the Magnetic Expansion of the Less Magnetic Metals." By P. E. **Shaw**, B.A., D.Sc. Communicated by Prof. J. H. Poynting, F.R.S.

Research has been made by various observers, notably Nagaoka and S. Bidwell, on the relation between field (H) and expansion per unit length ($\delta l/l$) resulting from that field of the metals iron, nickel and cobalt. Bismuth also has been tested, but the consensus of opinion is that it shows no expansion under any field so far applied to it. Outside the ferromagnetic group bismuth has the largest susceptibility (k) of any substance, and the tacit assumption seems to have been made that if bismuth shows no expansion, it is vain to look for it in less susceptible metals. But there is no direct relation between k and $\delta l\ l$; iron has maximum k six times as much as nickel, and yet expands far less than it for any known field, and so on.

It seems possible, therefore, that there may be appreciable movement for large fields in the case of metals other than the ferromagnetics. This paper gives an account of tests applied to specimens of bismuth, silver, aluminium, copper, zinc, brass, bronze, lead and tin. It is very difficult in working with large fields to avoid movements due to induction and attraction of iron (if any) in the apparatus, or to solenoidal suction or to a straining of the magnetising coil to set itself in the earth's field. These movements are small, but the apparatus is very sensitive, as it measures any movement more than 4×10^{-9} of the length of the specimen (19 cm.). The measuring instrument was the electric micrometer. By great care and repeated change in the arrangement these sources of error were eliminated, and it was found that no movement (more than the amount stated), positive or negative, occurs for any field up to the large one of 1900 C.G.S. No previous tests have been applied to any of these metals except bismuth. Bidwell has tested this metal with a field of 1500 C.G.S., and with a measuring apparatus which would show a movement of $1{\cdot}4\times10^{-8}$ of the length of the specimen, yet no movement was found. No other test has been so searching as the above. This definite negative conclusion involves two corollaries. (*a*) It is generally supposed that the small impurity of iron occurring in commercial pure metals would produce expansion on its own account which would mask any small expansion of the metal, but these experiments show no such expansion, and do not confirm the simple superposition theory. (*b*) The Maxwell strain $B^2/8\pi M$ cannot exist in the material rods tried, or it would have been easily detected, so we have fresh evidence that there is no mechanical connection, unless an extremely weak one, between matter and ether.

A note is appended to the paper in which Mr. G. A. Schott calculates the correction factor which must be applied to the ordinary expression for field $H=4\pi n\gamma$, when the field is taken over the whole length of the coil used.

Royal Society.—"The Maximum Order of an Irreducible Covariant of a System of Binary Forms." By A. **Young**. Communicated by Major P. A. MacMahon, D.Sc., F.R.S. Received September 26.

CAMBRIDGE.

Philosophical Society, October 26.—Dr. Baker, president, in the chair.—On nutrition and sex determination in man, by Mr. R. C. **Punnett**. Making use mainly of the London census of 1901, the author showed that if the various boroughs were divided into three groups of increasing poverty, the proportion of male to female births was least in the poorest and greatest in the wealthiest of these groups—in other words, the better the nutrition the greater the proportion of male births. It was shown, however, that there are certain factors, *e.g.* infant mortality, birth rate, and marriage age, which influence the above three groups unequally. When allowance is made for these factors it is likely that the proportion of the sexes produced in each group would be nearly identical, from which was inferred the improbability of different conditions of nutrition affecting sex determination in man.—Note on the action of radium rays and light on mercurous sulphate, by Mr. S. **Skinner**.—Note on the pulverisation of *nickel grains* in fuming nitric acid, by Dr. W. A. **Hollis**.—On the specific heat of gaseous carbon dioxide at high pressures under constant volume, by Mr. W. A. D. **Rudge**.—On some minerals from the Binnenthal, Switzerland, by Mr. R. H. **Solly**.—(1) The theory of the multiple gamma function; (2) the asymptotic expansion of integral functions of multiple linear sequence, by the Rev. E. W. **Barnes**.—The expression of the double zeta function and double gamma function in terms of elliptic functions, by Mr. G. H. **Hardy**.—On the kinetic theory of matter, by Mr. H. C. **Pocklington**.

PARIS.

Academy of Sciences, November 2.—M. Albert Gaudry in the chair.—On the non-regeneration of the spheridia in the sea-urchin, by M. Yves **Delage**. The experimental results described are in opposition to the hypothesis that the spheridia are the organs of equilibrium, since the removal of them does not permanently affect the powers of locomotion. Immediately after the removal of the spheridia the sea-urchins turn with more difficulty, but after some time it is impossible to distinguish them from others in this respect. This is not due to the regeneration of the spheridia, as there is no sign of them reappearing, three months after the operation.—Remarks on a communication of M. Raphael Dubois of October 19 last, by M. Edm. **Perrier**. Filippi was the first to state in 1852 that pearls were due to the presence of a parasite in the oyster, but his views were strongly contested. The results of the experiments of M. R. Dubois support this theory, and further confirmation is supplied from the laboratory of Rikitea.—Note by M. **Appell** on the second volume of his "Traité de Mécanique rationnelle."—On new effects produced by the *n*-rays; generalisation of the phenomena originally observed, by M. R. **Blondlot**. The *n*-rays are rays given off by various sources of light, capable of passing through an aluminium screen, and recognisable by their action upon a small electric spark or upon a feebly phosphorescent screen. It has now been found that these rays cause a slight but distinct increase in the luminosity of a feebly illuminated paper screen, and this effect is retained by the rays after reflection at a polished metallic surface.—On the virtual sugar of the blood, by MM. R. **Lépine** and **Boulud**. The carbohydrate present in the blood, measured by its reducing power and expressed as glucose, is frequently more abundant in the blood from the right ventricle than in arterial blood, and this contains more than blood from the veins.—The influence of mineral food upon the production of the sexes in diœceous plants, by M. Émile **Laurent**.—On left-handed

curves of constant torsion, by M. W. **de Tannenberg.**—On the determination of singular classes of Taylor's series, by M. Émile **Borel.**—On some points in the theory of *ensembles*, by M. Ernst **Lindelöf.**—On the relation between the pressure and the rate of chronometers, by M. Paul **Ditisheim.** It has been found that the variations in the rate are proportional to the differences in the pressure of the air. The action increases as the balance wheel is diminished, but tends towards a limit when the wheel is very small.—Remarks on the preceding paper, by M. Ch.-Éd. **Guillaume.** The effect produced would appear to be due to a small mass of air carried round with the balance wheel.—On the magnetic storm of October 31, by M. Th. **Moureaux.** The extreme amplitude of the variation is 0·0068 C.G.S. units for the horizontal component, and 0·0052 for the vertical component, numbers corresponding to 1/29 and 1/81 of the absolute values of these components.—On a variety of filiform carbon, by MM. **Constant** and Henri **Pélabon.** This form of carbon is formed from heavy hydrocarbons by the action of a very high temperature. It is attacked by fuming nitric acid and potassium chlorate.—On the separation and estimation of iron and phosphoric acid in water, by M. H. **Causse.**—On a method of synthesis of symmetrical dihalogen derivatives of benzophenone, by M. F. **Bodroux.** *p*-Dibromo-benzene treated with magnesium in the presence of dry ether gives $BrC_6H_4.Mg.Br$, and this with carbon dioxide gives a substituted benzoic acid and a ketone. Further examination of the latter has shown it to be symmetrical di-*p*-bromophenyl-ketone. At a very low temperature the acid is the chief product, the proportion of ketone produced increasing with the temperature.—The application of pyridine to the preparation of some amides, by M. P. **Freundler.**—On the use of magnesium amalgam in organic chemistry, by M. Louis **Meunier.** Details of the preparation of diphenylmethane and ethyl derivatives of malonic esters are given.—On orthotoluic aldehyde, by M. H. **Fournier.** This aldehyde is prepared in the pure state by the oxidation of the corresponding alcohol.—On the coagulation of starch, by MM. J. **Wolf** and A. **Fernbach.**—The olfactory sense of the snail (*Helix pomatia*), by M. Émile **Yung.** The sense of smell is, as a rule, limited to a distance of 2 to 3 cm.—The osmotic regulation of the internal liquids in Echinoderms, by MM. Victor **Henri** and S. **Lalou.** The results show that all the membranes which separate the internal fluids of the sea-urchins from the external liquid are semi-permeable.—On the fatty materials and the acidity of flour, by M. **Balland.**

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 12.

MATHEMATICAL SOCIETY, at 5.30.—Annual General Meeting.—On Sequences of Sets of Intervals containing a Given Set of Points: W. H. Young.—On Spherical Curves: H. Hilton.—On the Weddle Quartic Surface: Dr. H. F. Baker.—A Formal Generalisation of Maclaurin's Theorem: Rev. F. H. Jackson. Diffraction: W. H. Jackson.—A General Theorem concerning Absolutely Convergent Series: G. H. Hardy.—Note on Borgnet's Method of Dividing an Angle in an Arbitrary Ratio: Prof. J. D. Everett.—On an Expression of the Electromagnetic Field by Means of Two Scalar Potential Functions: E. T. Whittaker.—The Propagation of Wave-motion in an Isotropic Elastic Solid Medium: Prof. A. E. H. Love. Notes on Quaternions, including a Simple Construction for $V\alpha\beta\gamma$: Prof. R. W. Genese.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Inaugural Address by the President, Mr. Robert Kaye Gray.

FRIDAY, NOVEMBER 13.

PHYSICAL SOCIETY, at 8. (1) Means for Electrifying the Atmosphere on a Large Scale: (2) an Arrangement for driving Mercury Pumps: Sir Oliver J. Lodge and Benjamin Davies.

ROYAL ASTRONOMICAL SOCIETY, at 5.—Observations of Mars in 1903: Rev. T. E. R. Phillips.—Observations of Variable Stars; edited by H. H. Turner: Sir C. E. Peek (the late).—Ephemeris for Physical Observations of the Moon, 1904: A. C. D. Crommelin.—Results of Double Star Measures, 1902: J. Tebbutt.—Systematic Proper Motions of Bright Stars relatively to Faint Stars in the Oxford Zones (+25° to +31°): H. H. Turner.—Measures of Southern Double Stars, 1902–3: J. L. Scott.—Observations of Borrelly's Comet (*c* 1903): Natal Observatory.—Remarks on a Paper by Mr. Cooke on a New Method of Determining Time, Latitude and Azimuth: E. B. H. Wade.—Preliminary Note on the Effect of the Direction of Gravity on Lunar Observations: E. B. H. Wade.—A Spectrographic Study of β Libræ: Rev. W. Sidgreaves.—Observations of White Spots on Saturn: A. S. Williams.—*Promised Papers*:—Note on a Method of Photographing the Moon and surrounding Stars: H. H. Turner.—Errors in the Moon's Tabular Longitude from 1750: P. H. Cowell.—On the Large Sun-spots of 1903 October and November, and Associated Magnetic Disturbances. Communicated by the Astronomer Royal: Royal Observatory, Greenwich.—Note on Photographs of Comet *c* 1903 (Borrelly). Communicated by the Astronomer Royal: Royal Observatory, Greenwich.

TUESDAY, NOVEMBER 17.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Discussion of Paper on Tensile Tests of Mild Steel, and the Relation of Elongation to the Size of the Test-bar: Prof. W. C. Unwin, F.R.S.

ZOOLOGICAL SOCIETY, at 8.30.—Note upon the Tongue and Windpipe of the American Vultures, with Remarks on the Inter-relations of the Genera Sarcorhamphus, Gypagus and Cathartes: F. E. Beddard, F.R.S.—On the Mammals of Cyprus: Miss Dorothy M. A. Bate.—Report on the Fishes collected by Mr. Oscar Neumann and Baron Carlo von Erlanger in Gallaland and Southern Ethiopia: G. A. Boulenger, F.R.S.

ROYAL STATISTICAL SOCIETY, at 5.30.—Annual Presidential Address: Major Patrick G. Craigie, C.B.

MINERALOGICAL SOCIETY, at 8.—On Sartorite, Anatase, Galena and other Minerals from the Binnenthal: R. H. Solly.—On the Pleochroism of Adamite: L. J. Spencer.

WEDNESDAY, NOVEMBER 18.

CHEMICAL SOCIETY, at 5.30.—Constitution of Ethyl Cyanacetate. Condensation of Ethyl Cyanacetate with its Enolic Form: P. Remfry and J. F. Thorpe.—The Action of Water and Dilute Caustic Soda Solutions on Crystalline and Amorphous Arsenic: W. T. Cooke.—The Union of Carbon Monoxide and Oxygen, and the Drying of Gases by Cooling: A. F. Girvan.—Note on a Double Chloride of Molybdenum and Potassium: G. G. Henderson.—Simplification of Zeisel's Method for the Determination of Methoxy- and Ethoxy-Groups: W. H. Perkin, Senr.—The Action of Benzamidine on Olefine β-Diketones: S. Ruhemann.

GEOLOGICAL SOCIETY, at 8.—On the Occurrence of Edestus in the Coal-measures of Britain: E. T. Newton, F.R.S.—Notes on some Upper Jurassic Ammonites, with special reference to Specimens in the University Museum, Oxford: Miss Maud Healey.

SOCIETY OF ARTS, at 8.—Opening Address of the 150th Session: Sir William Abney, K.C.B., F.R.S., Vice-President and Chairman of the Council.

ENTOMOLOGICAL SOCIETY, at 8.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—The Great Dustfall of February 21 and 22, 1903, and its Origin: Dr. Hugh Robert Mill and R. G. K. Lempfert.

ROYAL MICROSCOPICAL SOCIETY, at 8.—Miscroscopic Resolution: Prof. J. D. Everett, F.R.S.—The Mouth Parts in the Nemocera and their Relation to the other Families in Diptera: Walter Wesché.

THURSDAY, NOVEMBER 19.

VEGETATION IN HERCYNIA.

Die Vegetation der Erde. vi. Der Hercynische Florenbezirk. Von Dr. Oscar Drude. Pp. xix + 671; mit 5 Vollbildern, 16 Textfiguren, und 1 Karte. (Leipzig: W. Engelmann.) Price 30 marks; Subscription price 20 marks.

THIS work is an elaborate monograph on the distribution of the vegetation in the Hercynian district of Germany, and forms the sixth volume in Drs. Engler and Drude's series "Die Vegetation der Erde." Dr. Oscar Drude, the author, the professor of botany at Dresden, has long been an accepted authority on the various problems connected with plant geography. In his "Deutschlands Pflanzengeographie," published in 1895, he defined seven regions of vegetation in the German flora, and in the present work he deals much more exhaustively with the mountainous and hilly country which stretches from the Hartz to the Rhön, reaching to Lausitz on the east and to the Böhmer Walde. The botanical literature of the area with which he deals is extensive, as it has been known to botanists ever since the time of Valerius Cordus, who was born in 1515. In 1588 Johann Thal wrote his "Sylva Hercynia," which was a catalogue of the plants growing in that district, and in the same year Joachim Camerarius published a work containing some curious coloured figures of some of the plants.

Dr. Drude divides the various Hercynian "Formationen" or plant habitats into ten main groups; these he again subdivides, making in all thirty-two. He carefully traces the absence or presence of these through the fifteen subdivisions of his geographical area. It may be well to indicate briefly the character of these ten groups (with one or two examples of the predominant vegetation of each), as their discussion occupies much of the volume.

Group i.—Woods of the low country and hills reaching 500 metres. Predominant vegetation:—Fagus, Quercus, Carpinus. Accessory:—Ulmus, Tilia, &c. The first subdivision of this group contains many shrubs, Cornus, Caprifoliaceæ and Rosaceæ, and is specially prevalent in Hesse and South Hanover, Thuringia, and parts of Upper Saxony.

ii.—Woods within the inundation area of rivers, &c., upper limit about 500 metres. Alnus, Betula, *Populus tremula*, &c., while Fagus is absent. The first subdivision of this group is almost absent in the Hercynian highlands proper.

iii.—Woods from 1100–1360 metres. Fagus, *Acer Pseudo-platanus, Picea excelsa, Abies pectinata,* the latter species wanting in certain districts. This group, in all its subdivisions, predominates in the Hercynian highlands proper.

iv.—Sandy plains and heaths. Calluna, *Vaccinium Myrtillus,* and *V. Vitis Idaea.* Predominates in Hesse and South Hanover, Thuringia and Upper Saxony, but present to a very small extent in the Hercynian highlands.

v.—Sunny hill formation. Carpinus, Tilia, and *Quercus sessiliflora,* species of Teucrium, Thymus, Helianthemum, and Dianthus. The first three subdivisions of this group predominate in Hesse, South Hanover, Thuringia, and Upper Saxony, but with slight exception are absent in the Hercynian highlands.

vi.—Wet meadows, &c. Hydrophilous, Poæ, Cyperaceæ, and Juncaceæ.

The first subdivision of this group contains Dactylis, Phleum, *Avena elatior, Festuca elatior* and *arundinacea*, and occurs in all the subdivisions of the geographical area with the exception of the Bohemian forests.

vii.—Turf moors. Hydrocotyle, Rhynchospora, and *Gentiana Pneumonanthe.* Hill turf moors are absent in Thuringia and Upper Saxony.

viii.—Subalpine Hercynian hill formation, 900–1450 metres. *Lycopodium alpinum* and *L. Selago,* also *Empetrum nigrum.* The two subdivisions of this group predominate in the Hartz Mountains, in the Erz, and in the Bohemian Forest.

ix.—Inland watery situations. Nymphæa, Hydrocharis, Typha, Heleocharis, and Littorella. The first three subdivisions of this group predominate in Hesse, South Hanover, Upper Saxony, and to some extent are present in the Hercynian highlands. The last subdivision of the group, saltmarshes, &c., of which the characteristic vegetation is *Aster Tripolium, Triglochin maritimum*, Salicornia, *Obione pedunculata,* &c., is present in Hesse, South Hanover, Thuringia, but absent in Upper Saxony and the Hercynian highlands.

x.—Cultivated ground. Chenopodiaceæ, Solanaceæ, *Centaurea Cyanus, Agrostemma Githago,* and *Neslia paniculata.* Present in all the subdivisions of the area except the Bohemian forest.

The flora of Hercynia does not differ very materially from that of Britain, and nearly all the plants are lound in similar situations in this country, so the volume is well worth the attention of our own local ecologists.

Fifteen chapters of the book are devoted to various portions of the geographical area, as, for instance, Das Weser Bergland, Das Braunschweiger Hügelland, and Hügelland der Werra and Fulda mit der Rhön, &c., and under each are discussed their orographic and geognostic character—the formations that occur in the area and the topography. Perhaps one of the most interesting of these chapters is that on the Hartz Mountains.

The Hartz is a detached chain, flat on the top, 2000 feet above the sea, with a number of peaks rising out of this, among which the Brocken, 3733 feet above the sea, is the highest. Its geological composition is granite. On p. 497 we have a figure showing the character of the vegetation surrounding the summit. The Weser Mountains are lower, averaging not more than 600 feet, the highest point being 1500 feet. The Rhöngebirge and several basaltic ridges are also low.

Many years ago it was pointed out that the Hartz Mountains present some curious peculiarities in their vegetation which deserve especial notice. In order to comprehend them in their true independence, we must

exclude the low promontories and ranges of hills around the great mass, since the vegetation of these, both geologically and botanically, agrees with those of the terraces of the Elbe and the Weser. The uniformity of structure of the great central mass of the Hartz, the rarity of lime, &c., causes a comparative poverty of peculiar forms of flowering plants, but, on the other hand, a subalpine character may be detected, and this at a height above the sea which would not lead one to expect it. Another feature, long ago pointed out, is the depression of the climatic tree-limit. Dr. Drude gives the following list of the twenty-four rarer or characteristic species of the Brocken flora :—*Listera cordata, Epipogon aphyllus, Trichophorum caespitosum, T. alpinum, Carex pauciflora, ? C. Heleonastes, C. rigida, C. limosa, C. sparsiflora, Geum montanum, Linnaea borealis, Hieracium alpinum, H. nigrescens bructerum, Andromeda poliflora, ? Pinguicula alpina, Pulsatilla alpina, Empetrum nigrum, Rumex arifolius, Thesium alpinum, Salix bicolor, Betula nana, Lycopodium alpinum, Selaginella spinulosa,* and *Athyrium alpestre.*

Saxifraga Hirculus was found by Kohl in the neighbourhood of Zorge in 1809, but does not seem to have been gathered by anyone since that date, and many other interesting notes on individual species are given.

Hampe, in his "Flora Hercynica," gives 1343 vascular plants as occurring within his area, and there is a good deal of additional information on the distribution of plants in this region in A. Andree's little pamphlet "Die Flora des Hartzes und des Östlichen Vorlandes bis zur Saale."

The Erzgebirge, a chain of mountains mostly of primary formation, are on the south-east of the area taken by Dr. Drude. A long list of the characteristic species is given, from which we select the following as particularly worthy of note :—*Orchis globosa, Herminium Monorchis, Coeloglossum viride, Gymnadenia albida, Listera cordata, Corallorhiza innata, Lilium bulbiferum, Streptopus amplexifolius, Polygonatum verticillatum, Luzula silvatica, L. sudetica, Trichophorum caespitosum, Carex pauciflora, C. rigida, C. supina, C. limosa, Calamagrostis montana, Poa sudetica, Scheuchzeria palustris,* &c.

Meum athamanticum, Orchis globosa, Gentiana spathulata, and *Phyteuma orbiculare,* which are present in the Erzgebirge, are wanting in the Upper Böhmer Walde, and only the Meum and the Phyteuma reach the Hartz. *Senecio crispatus,* in the Thuringen Wald, reaches its northern limit in Hercynia, but it is impossible in a brief notice to give any idea of the mass of detailed information which Dr. Drude has here collected together.

Much good work has recently been published on the distribution of plants in various portions of the globe. In Central Europe there have been the preceding volumes in the present series, Prof. Moritz Willkomm's "Iberian Peninsula," Dr. Pax's admirable work on the Carpathians, Dr. Gustav Radde on the Caucasus, Dr. Beck on the various countries included under Illyria, and Dr. P. Graebner on north Germany. In the United States we have had Prof. MacMillan's "Minnesota Plant Life," "The Plant Life of Alabama" by Dr. Möhr, and a report on the Dismal Swamp region by Mr. Thomas H. Kearney. In this country the late Robert Smith mapped out three districts in Scotland, and his brother, Dr. W. G. Smith, of Leeds, and his colleagues have already mapped out two districts in Yorkshire, and given lists, illustrated by photographs, of the characteristic plants of the different stations. A first instalment of a botanical survey of the basins of the rivers Eden, Tees, Tyne and Wear, by Mr. F. J. Lewis, was lately read at the British Association, and we hope the contemplated survey of the Pennines, from Derbyshire to the Cheviots, will be successfully carried out.

Dr. Drude in Hercynia has done his work most fully and conscientiously. Every possible plant-association connected with every varying physical condition of the country has been carefully noted, and both its phenogamous and cryptogamous constituents have been determined. But we feel that the work may somewhat bewilder the ordinary reader by reason of its excessive elaboration. E. G. B.

MEASUREMENT BY LIGHT WAVES.

Light Waves and their Uses. By A. A. Michelson. The Decennial Publications of the University of Chicago. Pp. 166. (Chicago: University Press, 1903.) Price 2 dollars net.

THE University of Chicago, in commemoration of the completion of the first ten years of its existence, is publishing a series of volumes dedicated "to the men and women of our time and country who by wise and generous giving have encouraged the search after truth in all departments of knowledge."

The publication committee is to be congratulated in that it has persuaded Prof. Michelson to contribute a volume to this series. Anything that he writes is sure to be worth careful and attentive study, and while the actual scientific results recorded do not, as a rule, in any way claim to be new, Prof. Michelson has succeeded in putting the important consequences of his own inimitable work in a manner which will render them known to many who could hardly be expected to follow the original papers.

The volume contains eight lectures delivered at the Lowell Institute in 1899. It starts with an elementary account of light waves and their properties, and in the first lecture some of the consequences of the principle of interference are skilfully developed.

But the distinctive tone of the work is not noticeable until we come to Lecture ii., which deals with a comparison of the microscope and telescope with the interferometer.

An account is given of the action of a lens, and the theory of the diffraction fringes formed by a microscope or telescope objective is outlined. This leads to the theory of the resolving power of a microscope, and to the conclusion that, while 1/250 of an inch is the limit of resolution for the human eye, that of the microscope is one four-hundredth of this, or about one hundred-thousandth of an inch. It is then shown that by limiting the aperture of a telescope to two parallel slits near the opposite ends of a diameter, the fringes formed become more distinct, though with a considerable loss of light, and from this the action of various

forms of interferometer in which the interfering pencils are separated and then reunited after reflections at a series of plane mirrors is deduced. It is explained, further, that with such instruments the accuracy of measurement possible with a telescope or microscope can be greatly exceeded, and that, too, without serious loss of light.

The application of interference methods to various measurements forms the subject of the remaining lectures.

One of the features of the Edinburgh meeting of the British Association in 1892 was Michelson's paper on the application of interference methods to spectroscopic research read before Section A and printed in full among the reports.

Fizeau had years before explained the gradual disappearance and reappearance of Newton's rings when formed by sodium light between a flat surface and a lens of small curvature as the distance between the two is increased. It is due to the fact that the D line is double; the ring system seen, therefore, is a complex one produced by the superposition of the two systems due to each line separately. When the bright rings of the two systems coincide, the visibility of the rings is a maximum; as the distance between the lens and plate is increased, the bright rings of the first system overlap the dark rings of the second, the intensity of the field becomes uniform, and the rings cease to be visible.

Michelson defined the visibility of the ring system and showed how it depends on the distribution of light in the source; he then proceeded to measure experimentally the visibility of the rings formed by various spectrum lines, and from this to analyse the distribution of light in the lines. By a stroke of genius he utilised the defects of the ring system to advance our knowledge to a surprising extent. Lecture iv. contains a most interesting account of his work.

The chapters that follow are no less fascinating; thus the next lecture describes the measurements undertaken by Michelson at the Bureau International des Poids et Mesures at Sèvres to determine the relation between the wave-length of cadmium light and the standard metre; cadmium light was chosen because of the simplicity of the lines of its spectrum, and it was shown that in air at 15° C. and at normal pressure the number of waves in a metre is for the red ray of cadmium 1553163·5, for the green ray 1966249·7, and for the blue 2083372·1. The absolute accuracy of these results is said to be about one part in two millions, the relative accuracy about one part in twenty millions.

In Lecture vii., application of interference methods to astronomy, it is shown how an examination of the visibility curve of a star enables the observer to detect double stars which are far too close to be resolved by any telescope, while the last lecture, on the ether, deals with a problem which is yet unsolved, the theory of aberration.

The aberration constant, the ratio of the velocity of the earth to that of light, is a quantity of the order 1/10000, and its accurate measurement had proved no easy task. Michelson, with the view of solving the question whether the earth is at rest or in motion relative to the ether at its surface, undertook a measurement which involved the square of this tiny quantity, or one part in one hundred millions, and carried it out successfully. The result of the experiment was to show that this relative motion, if it exists at all, must be extremely small, and that the ordinary explanation of aberration, which assumes that the ether remains at rest while the earth moves through it without disturbing it, is untenable. The only solution of the difficulty yet offered is that due to Lorentz and Fitzgerald, who pointed out, independently, that the motion of a body through the ether might, on certain assumptions as to the connection between ether and matter, cause the body to contract in the direction of motion, and that this contraction would depend on the square of the aberration constant, so that its effect might compensate for the effect looked for by Michelson.

In his first lecture the author apologises for using, as illustrations of his subject, his own researches.

"I do this," he says, "because I believe I shall be much more likely to interest you by telling what I know than by repeating what someone else knows."

Prof. Michelson has earned our thanks for putting some of his knowledge into so attractive a form; he will perhaps forgive us if, in closing, we express the wish that he will tell us more of what he knows.

R. T. G.

ALL ABOUT CATS.

The Book of the Cat. By Miss F. Simpson. Pp. viii+380; illustrated. (London: Cassell and Co., Ltd., 1903.) Price 15*s.* net.

THE "cult of the cat" has of late years increased to such an enormous extent that there can be no doubt as to the need for a thoroughly trustworthy and exhaustive account of the various breeds kept in this country, together with notices of those of other lands. Of this favourable opportunity Miss Simpson has taken full advantage in the handsome and beautifully illustrated volume before us, the exceedingly low price of which places it within reach of fanciers in all ranks of life. In addition to the description of the various breeds kept in this country, the author has also given chapters on the feeding, housing, and general treatment of cats (derived from her own extensive experience), as well as on the management of cat-shows; while other chapters by various specialists are devoted to foreign breeds, the cat's place in nature, and the diseases of cats and their treatment. The book is therefore a compendium of all that relates to domesticated cats, and it may be almost said that it contains practically all that is worth knowing about these animals.

Perhaps the least satisfactory portion of the book, so far as Miss Simpson is concerned, is to be found in the opening lines of the first chapter, where we find the statement that the origin of the cat has long puzzled the learned, and is still a zoological mystery. Neither does the second sentence—"Historians tell us that the feline race came into existence about the same

time as the horse"—tend in any way to mend matters. Moreover, when we turn to the chapter on some foreign cats, by Mr. H. C. Brooke, we find it stated, although somewhat guardedly, that the Egyptian cat is the probable ancestor of our domesticated breeds. There does not, therefore, seem to be complete accord in this respect between the two authors, and we venture to suggest that, although the pedigree of the original British breed of cat cannot be fully traced, the term "mystery" is scarcely appropriate to the real facts of the case. In this connection mention may be made of Mr. Brooke's error in referring (p. 297) to the European and Egyptian wild cats as "varieties" instead of "species." It is perfectly true that the mistake, in analogous cases, is very frequently made by amateur zoologists, but it is nevertheless quite inexcusable.

Passing over the chapters devoted to the housing and exhibition of cats, our attention may be directed to what Miss Simpson has to say with regard to the various breeds kept in this country. The first group taken into consideration is that of the long-haired or Persian breeds, of which quite a number of different strains, chiefly or entirely distinguished by colour, are recognised by fanciers. The author is of opinion that no satisfactory distinction can be drawn between Angora and Persian cats, and in this she is doubtless right. No reference is, however, made to the opinion current among zoologists that the Persians very probably trace their origin to the long-haired Pallas's cat (*Felis manul*) of Central Asia, which, with the exception of the tail and limbs, is a nearly uniformly coloured species. Neither is enough made of the fact that all imported Persians appear to be uniformly coloured, although a quotation from Mr. Harrison Weir to this effect is given. If this be really the case, there can be no doubt that all Persians with "tabby" and "tortoise-shell" markings are due to a cross between the pure breed and European cats. Strong confirmation of this is afforded by a statement of the author to the effect that so-called orange Persians tend to lose their markings and become uniformly coloured.

Under the heading of Manx cats the author alludes to the current belief that these are due to a cross between a cat and a rabbit! A whole chapter is devoted to the beautiful Siamese cat, although no reference is made to its possible origin from the bay cat (*F. badia*). To the author's account of ordinary short-haired cats we need not refer, and the remaining space at our disposal must be devoted to foreign cats (other than those kept in this country). Mr. Brooke, in chapter xxvi., has been fortunate in securing some very interesting photographs, notably those of the Burmese and Abyssinian breeds, the latter of which is also represented in a coloured plate, together with an Indian cat. Most remarkable of all is, however, the photograph of hairless New Mexican cats, now said to be all but, if not quite, extinct.

Although the book might have been improved if the proofs had been submitted to a zoologist, there can be little hesitation in pronouncing it a decided success, and indispensable to every student and breeder of cats.

R. L.

AMERICAN RAILWAYS.

American Railways. By Edwin A. Pratt. Pp. viii+309. (London: Macmillan and Co., Ltd., 1903.) Price 3*s*. 6*d*. net.

AS it appears to be the fashion just now to look upon British railroad management as antiquated, and its methods effete, it is interesting to study a book dealing with American practice, as its adoption in this country is looked upon by some as the only salvation of British railways from a dividend earning point of view.

The volume before us deals with the general question in a fair and open manner. Mr. Pratt evidently went to the States with the intention of seeing as much as possible, and comparing what he did see with home practice; he gives us in his book a very readable account of the result.

The big waggon question is, of course, interesting, and we read that twenty-five years ago the average freight box waggon in the United States had a capacity ranging from 16,000 lb. to 24,000 lb. Then, in 1881, the 40,000 lb. waggon was introduced, this being followed in 1885 by the 60,000 lb. waggon. After this, in 1898, a waggon, though no larger than its predecessors, was so constructed as to have a capacity of 80,000 lb., and to-day waggons are being extensively used with a capacity of 100,000 lb. This continual increase in waggon capacity is well illustrated by means of tables. The dead weight is gradually being reduced, and in the case of pressed steel waggons the proportion of paying weight to the total weight of the car when loaded is 73 per cent., and it is interesting to know that waggons of this type are being gradually introduced into this country, the most satisfactory being those designed and made by the Leeds Forge Company.

With the rapid increase in the weight of trains hauled came the heavier and more powerful locomotive, and it is here where the American locomotive engineer has the advantage of his British brother, it being possible for the American engine to be both higher and wider than the British engine, thus materially increasing its capacity.

We read that the majority of American officials with whom the author discussed the big waggon question did not care to commit themselves to any recommendation of the use of such large waggons in Great Britain. The nearest approach is the American type of enlarged freight waggon for the transport of coal from the collieries to the sea, and these are now being successfully used by the North-Eastern Railway.

An important conversation with a prominent official is reported on the general question of handling of traffic in the two countries. He said, ours is wholesale business, yours is retail. We get bigger lots than you do, and we can handle them to better advantage; but in regard to general merchandise your arrangements are far better than ours, &c. It is evident, therefore, that the conditions are so very different that the mere adoption of American methods *en bloc* is not sufficient in itself. No doubt there are many practices which can be assimilated with advantage, and these can only be discovered and thought out by sending

picked railway men on a tour of inspection over the American railways.

Chapter xx. is of value. The author gives us the benefit of his "conclusions," and states that

"before starting on my tour of the United States I had heard or read so much in praise of the conditions existing on American railways that I expected to bring back with me a long list of recommendations deserving consideration on this side. But the more I looked for and inquired after any special advantages that were really suited to British conditions, and desirable of adoption here. the greater my difficulty in finding or learning of any became."

There is no doubt, however, that the British railways are only too anxious to learn, for most of the important lines have sent their officials to study on the spot and to investigate anything that is new.

We can recommend this book to all students of railway practice as one containing much useful information and decidedly worth reading. N. J. L.

OUR BOOK SHELF.

Why the Mind has a Body. By C. A. Strong. Pp. x+355. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1903.) Price 10s. 6d net.

IN this book Prof. Strong deals with the riddle of the universe, and contributes some original ideas toward its solution. Of the three sections into which the work is divided, the first deals with the current theories of automatism, parallelism, and interaction, and criticises them on their merits; the second gives us a metaphysical ground-work; the third resumes criticism on the bases of the results of the second part, and develops the new doctrine. The critical part must be left to the reader, who will not fail to find it vigorous and interesting; as the peculiar features of the author's thought emerge most clearly in the constructive work, our space will be best used in indicating these ideas.

The goal is psychophysical idealism, which is metaphysically monistic, but distinct from psychophysical monism. The world, as we then have it, is monistic in "stuff" and in "form"; in form, for the theory "conceives individual minds and other things-in-themselves as together constituting a single system"; in stuff, for all is mental. This conclusion rests on the doctrine of things-in-themselves which the second section is designed to prove. As to these, the nature of reality is known to us in consciousness; they are therefore not unknowable; we also have a transcendent knowledge of other minds, hence we know some extra-mental realities, and are saved from solipsism. Two such realities may stand in a causal relation each to each; Kant's limitation of causality to the sphere of experience applies only to phenomenal causality; but there is also a real causality to which this limitation does not apply which may be used to transcend experience. If we now ask how the causal chain, *e.g.* from A's anger to B's sensation of pain, is to be constructed, we find a gap which requires filling; hence a "cosmological proof" of other things-in-themselves which must be mental but are not consciousnesses.

It must be left to the reader to follow these arguments in detail; the bare outline here given will serve to show the trend of thought; the whole is not unworthy of the slightly paradoxical title. The author is always attractive, and his style is vigorous, though at times Transatlantic in diction; he anticipates the possibility of failing to convince his readers, in which he is not without justification, for he deals with the obscure obscurely. The most fundamental and most difficult point is the relation of one consciousness to another; here we have a "transcendent" knowledge hitherto overlooked by philosophers. This knowledge is founded "neither on reason nor experience, but solely on instinct" (p. 219). Deeper still, our own past experience stands to us in the same relation as another consciousness; "it literally *is* another consciousness, though one no longer existent" (p. 222). We reach this by a conjecture which bears "the closest analogy to the process by which we infer other minds" (p. 222). Then is our "instinct" after all an inference? And if we know another consciousness because it in some way acts upon us, do our own past experiences also in some way act upon us? As this is not a criticism, the question may be left without discussion. What should be noted is that, though we find the self-development of mind rejected, the evolution of things-in-themselves accepted, though we hear of the "imprinting" achieved by things upon minds (which seems convertible with evoking states of consciousness), we nowhere have a discussion of the problem of activity; that is why our gratitude for this work does not obliterate the feeling that one riddle has been solved by—another. G. S. B.

The Position of the Old Red Sandstone in the Geological Succession. By A. G. M. Thomson, F.G.S. Pp. vi + 224. (Dundee: John Leng and Co., 1903.)

MORE than sixty years ago Hugh Miller, in his classic on "The Old Red Sandstone," remarked, "There are some of our British geologists, too, who still regard it as a sort of debatable tract, entitled to no independent status. They find, in what they deem its upper beds, the fossils of the Coal Measures (*i.e.* Lower Carboniferous), and the lower graduating apparently into the Silurian System; and regard the whole as a sort of common, which should be divided as proprietors used to divide commons in Scotland half a century ago, by giving a portion to each of the bordering territories." One object of the present work is to show that the conditions under which the Old Red Sandstone was produced may not have been of the character of inland lakes without free connection with the sea; and another object is to show that these conditions may not have begun only after the close of those which produced the highest Silurian strata, nor have terminated before the date of deposition of the oldest of the Carboniferous beds.

It would seem as if we had made very little progress during the past sixty years, and, to a certain extent, this is true. The ancient physical geography of the Old Red Sandstone period has yet to be clearly depicted, and the precise relations of Old Red Sandstone and Devonian to Silurian and Carboniferous still require further detailed research among the fossil plants and animals, and among the rocks in which these organic remains are entombed. A book should in this, as in all other cases, be either useful or interesting, or it might, as with Hugh Miller's works, possess both attributes. The present work, however, seems to fail in both respects. The expressions used by the author, of "Prevertebrate" and "Vertebrate Silurian," "Prevertebrate" and "Vertebrate Old Red," eleven times on one page, and often six or seven times, and in one instance varied by the printer into "Pervertebrate," are, to say the least of it, tiresome. We read also of "Vertebrate Palæozoic times" and "'Vertebrate Old Red' rivers."

The work is mainly a discussion with regard to the distribution and succession of life, and with regard to the physical conditions, bearing on the objects previously expressed. It may afford some new suggestions to those studying the Old Red Sandstone, but it lacks precise stratigraphical evidence and tabula-

tion of facts. Too many sentences commence with "Suppose," or "It would not be surprising," or "It is just possible," or words with a like significance. If the author had put his views into an essay of ten or twelve pages, he would have done more to further his object, in which we cordially sympathise, of arriving "at the truth concerning the position of the Old Red in the succession."

Steel and Iron for Advanced Students. By Arthur H. Hiorns. Pp. xvi + 514. (London: Macmillan and Co., Ltd., 1903.) Price 10*s*. 6*d*.

EVIDENTLY based upon a course of lectures delivered at the Birmingham Municipal Technical School, this little book is primarily a text-book not of so highly advanced a character as the title might perhaps suggest. It is well up to date, and embodies the latest views on the subject expressed at recent meetings of the Iron and Steel Institute. The arrangement of the matter is very similar to that adopted in Bauerman's "Metallurgy of Iron" and in Greenwood's "Steel and Iron." The 131 illustrations are admirable, and well adapted to indicate to the student or intelligent workman the principles described. The index is the least satisfactory part of the book. The names of several authors cited (Brinell, Brustlein, Carvès, Chênot, Eyermann, Hoffmann, Lürmann, Massicks and Crooke, Mukai, McWilliam and Pourcel) are incorrectly spelt, whilst several authors to whom reference is made in the text (Berthier, Chernoff, Ewing, Faraday, Galbraith, Hautefeuille, and Wingham) are omitted. Similar errors in proper names occur in the text. Sir Lowthian Bell, for example, is described as Sir Lothian (p. 135) and as Mr. Bell (p. 380), and no distinction is made between Mr. Edward Riley and Mr. James Riley. Despite these faults, the book may be cordially recommended to science teachers as one which is eminently suitable for metallurgical classes.

Agriculture for Beginners. By C. W. Burkett, F. L. Stevens, and D. H. Hill. Pp. xii+267. (Boston and London: Ginn and Co., 1903.)

THE question of the introduction of instruction in agriculture or any other definitely technical subject into our elementary schools is one which has been much debated recently, but the opinion of most of those who have any working knowledge of teaching is very strongly against it. Agriculture in schools is very likely to become a book subject; it is far preferable to take up some question like the growth of a plant, which admits both of simple experiment on the part of the pupil and of abundant illustration from practical life, which again supplies a basis of reasoning and knowledge for anyone who happens in later life to be concerned in the raising of crops.

The authors, however, of the little book under notice consider that in the country schools of the United States something more definitely agricultural is wanted, since "most boys and girls reared on a farm get no educational training except that given in the public schools." They have, accordingly, prepared a text-book which, in the earlier stages, deals with the plant in the manner we have indicated, by simple experiments capable of repetition by the scholars. They pass on to more special topics, such as cross-fertilisation and the raising of new varieties, diseases of plants, insect pests, crops and stock, dairying, &c., all treated in a simple and attractive fashion, with a great wealth of illustrations, admirably selected and reproduced. The conditions dealt with are, however, so distinctively American as to render the book of little service in English schools, though the teacher himself may obtain from it some hints as to method and many excellent illustrations.

The Praxis of Urinary Analysis. A Guide to the Chemical Analysis of Urine. By Dr. Lassar-Cohn, Professor in the University of Koenigsberg. Authorised Translation by H. W. F. Lorenz, A.M., Ph.D. Pp. vi+58. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1903.) Price 1 dollar.

THE object of this little book is stated to be to give directions for the chemical determinations of the *ordinary* constituents of urine and of the stomach contents that are of value for diagnosis. Even with this limitation, the directions given are too brief, especially as regards those for quantitative estimations. For the detection of albumen the heat test, and for sugar Trommer's test, alone are mentioned. For the quantitative estimation of sugar, it is stated that titration with Fehling's solution is only suitable for chemical laboratories, because the solution must be freshly prepared, and, "secondly, and this is much more annoying, it is extremely difficult to determine the end of the reaction, for solutions of the proper strength can be bought nowadays" (p. 38). The translation must have gone astray here. As regards practical value, the two pages upon the quantitative estimation of sugar might have been omitted.

R. T. HEWLETT.

Studies in Physiology, Anatomy and Hygiene. By J. E. Peabody, A.M., Instructor in Biology in the Morris High School, New York City. Pp. xviii + 332; 147 illustrations in the text. (New York: the Macmillan Co.; London: Macmillan and Co., Ltd., 1903.) Price 5*s*. net.

THIS is one of a numerous class of books suitable for use in high schools and similar institutions. As its title implies, it gives, in addition to the principles of physiology, as much anatomy and also, it may be mentioned, chemistry as is necessary for the understanding of the bodily functions; the application of such knowledge to everyday life (hygiene) is also pointed out in a sensible and practical way. A book of this character does not call for any lengthy review; it is sufficient to say that after a careful perusal we are convinced that it will fulfil the *rôle* the author wishes it to play. It is clearly written, well illustrated, and, what is more important, is unusually free from errors.

Arithmetic. Part ii. By H. G. Willis, M.A. Pp. viii + 236 + xxxix. (London: Rivingtons, 1903.) Price 1*s*. 4*d*.

THE senior mathematical master of Manchester Grammar School here continues his plan of supplying examples in arithmetic grouped in series so as to furnish two or three lessons a week for a term. These exercises cover the parts of the subject studied in schools which were not dealt with in the author's former book. Oral questions are inserted at the beginning of each exercise, and answers to all examples are provided.

Arithmetical Types and Examples. By W. G. Borchardt, M.A., B.Sc. Pp. xii + 367. (London: Rivingtons, 1903.) Price 3*s*. 6*d*.

THIS volume is, the author states, intended to stand between the complete text-book of arithmetic and the mere compilation of examples. Each exercise is preceded by a model worked-out example, and a few explanatory notes are added. Most of the recommendations of the recent committee of the Mathematical Association have been adopted, and full answers are given. We notice that graphical methods are made use of, and logarithms are employed to facilitate the calculation of compound interest.

LETTERS TO THE EDITOR.

Heating Effect of the Radium Emanation.

A FORTNIGHT ago I wrote to you respecting the rise of temperature observed in radium compounds. I pointed out that the experiments of Profs. Rutherford and Barnes seemed to show that the effect was largely due to the excited activity. I have since then made a few experiments confirming that view.

Air charged with radium emanation was led through a tube in which I placed a thermal junction formed by iron and nickel wires. The junction was left charged to a high negative potential during about ten minutes, then taken out and placed side by side with an unexposed junction in a metal vessel kept at constant temperature by a water jacket. The two junctions at first seemed to be at the same temperature, but the exposed one began to become warmer almost immediately, and after twenty minutes was about one-tenth of a degree higher than the other junction. The experiment was repeated with the same result. Test experiments were made in various ways to show that accidental temperature disturbances could not affect the experiment. Thus, after the wire had been treated exactly in the same way in a current charged with thorium emanation, the junction showed absolutely no change of temperature detectable by the galvanometer used.

We may draw an important conclusion from these experiments. Prof. Rutherford has given strong evidence to show that the excited activity really contains three successive stages of radio-active matter, the first changing into the second, and the second into the third; the fact that the maximum heating effect was only obtained thirty minutes after the wire was first exposed to the emanation seems to show that it is the last transformation in which the third excited activity finally disappears or becomes inactive which sets the energy free. Experiments are now in progress to test the matter further.

The experiment mentioned above with the thorium emanation was not altogether satisfactory, and I should not at present like to draw the conclusion that the excited activity due to thorium does not give a heating effect. I only mention it here to show that the treatment of the wire in the experiment independently of the presence of radium does not give rise to such variations of temperature as have been observed. Had any appreciable amount of the heating effect been due to the contact with the emanation, I should have expected the junction to show some rise in temperature when first introduced to the calorimeter. All these results should be considered as provisional only until a more detailed investigation has been made.

ARTHUR SCHUSTER.

The Owens College, Manchester, November 14.

Radium and Animals.

IN the issue of NATURE of November 5, Mr. Dixon gave a brief account of some interesting experiments with radium upon seedlings and upon Volvox, the results of which were almost entirely negative. Like Mr. Dixon, I have been investigating the action of radium rays upon living matter, but in my experiments animals of simple structure have been employed instead of plants, and my experience leads me to think that the negative result of his experiments may have been due to the distance which separated the small quantity of radium he employed from the seedlings.

In my experiments, which I have been carrying out in the university physiological laboratory, three lots of radium bromide were used, 5 mgr., 10 mgr., and 50 mgr. respectively. These were brought within 3 mm. of the cells containing the animals, the walls of which were made of thin mica instead of glass in order to lessen the absorption of the rays.

It is too soon to discuss that obscure problem, the nature of the influence of the rays upon living matter, but it is already clear that experiments with simple forms of life will furnish some data.

I have endeavoured to determine (α) whether the rays would provoke an immediate response of the nature of a contraction; (β) whether they would evoke the more generalised "tactic" response—that is to say, whether they would repel or attract the animals. Put very briefly the results are as follows:—

(α) Actinosphærium, with pseudopodia extended, exposed in daylight to 10 mgr. radium at 3 mm. did not retract its pseudopodia. In two hours, however, it was dead and breaking up. Controls were unchanged.

Stentor—a green species. Two specimens were kept in the dark for some hours to increase their sensitiveness to radiant energy. On examination with a minimum of light the animals were found extended with cilia in rapid movement. Exposed to the rays from 50 mgr. of radium at 4 mm. both slowly contracted, and slowly extended on removal of the radium. This observation was repeated three times. After the third exposure one Stentor refused to extend.

(β) Stentor. Sixteen free-swimming specimens were placed in the dark in a cell over a lead plate 3 mm. thick with a hole in the centre about 5 mm. in diameter under which was 50 mgr. of radium bromide. Next day fifteen of the animals had attached themselves clear of the pencil of β rays, and one injured specimen was in the path of the rays.

The cell was then moved so that a group of five came into the path of the β rays. In a few hours these were found to have detached themselves and moved out of the rays.

Similar results were obtained on other occasions, though it seems possible for the rays to kill feeble specimens before they respond to the repelling influence.

Hydra, both *viridis* and *fusca*, will, as a rule, detach themselves and move out of a pencil of β rays. If, however, the animal is again moved back into the rays from 50 mgr. at 4 mm. distance the third immersion is usually fatal—the tentacles drop off and the body slowly breaks up.

Perhaps the most interesting result was obtained with *Euglena viridis*. Encysted specimens under the influence of radium rays (β and γ) in the dark readily become motile and disperse without suffering any harm.

Newnham College, Cambridge. E. G. WILLCOCK.

Note on the Arctic Fox (Canis lagopus).

A RATHER peculiar error in regard to this animal seems in danger of being perpetuated in certain contemporary literature, in which it is stated that, while in the other regions of its distribution the Arctic fox generally acquires a white winter coat, in Iceland this change never takes place, but that all the foxes there are blue. As a matter of fact, this fox turns white in the Icelandic winter as elsewhere, with this reservation only, that the proportion of blue winter forms there is greater than the proportion in the Arctic regions generally, the white forms, however, probably still remaining in an actual majority. I believe this occurrence of the white phase in Iceland is so far well known that I need not dwell on the evidence for it; from personal experience, however, I can corroborate it. It is a small point, but in so far as error is abroad, it seems advisable to correct it.

In Iceland I was informed that the white form and the blue were distinct, and in his work on this island a century and a half ago, Horrebow was of the same opinion. This view is based on the fact that both Horrebow and the Icelanders had seen white foxes in full summer, and is no doubt to be explained by the fact that occasionally the white dress is not changed for the summer brown. On the other hand, I believe that some authors still maintain the distinctness of the two forms, though I am not aware how they overcome the evidence of those who have observed the phases intermediate between the two which occur at the moulting season.

In his "Colours of Animals" Prof. Poulton quotes the

case of three Arctic foxes from Iceland in the Zoological Gardens, of which "one turns perfectly white every winter, while the other two remain dark."

Cambridge, November 12. W. F. LANCHESTER.

The Magnetic Storm of October 31.

DR. GLAZEBROOK has asked me to send you a copy of one or more of the magnetic curves during the late storm, and also of a characteristically "quiet" day. For the latter I send copy of declination October 2–3, 1900, B_1, Fig. 2. It is not absolutely quiet very few days are, if any—and parts show the tiny "magnetic waves" often met with. Here, as usual, there are two days' curves, each with its own base (or time) line on the same sheet. The paper is changed every second day, shortly after 10 a.m. In this quiet day declination curve, 1 cm. of ordinate in the original represents 8′.7, and increasing ordinate answers to increasing westerly declination.

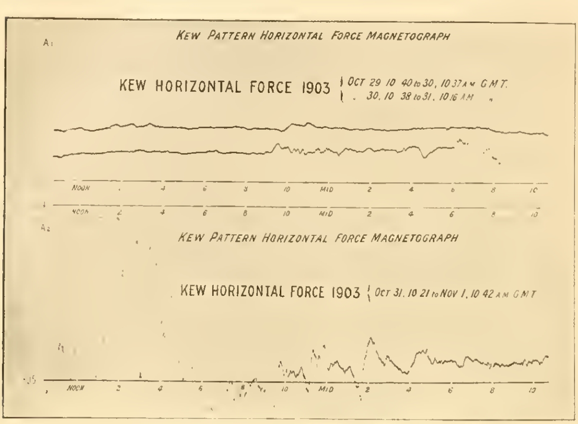

FIG. 1.—Reduced Registers of Horizontal Force.

The magnetic storm on October 31 commenced about four hours before the papers were changed, and the assistant in charge, noticing that a storm was in progress, arranged that the papers should be changed again next day, so as to have only one day's trace on the sheet, and so no mixing of two days' traces. As the commencement at 6.3 a.m. is of interest, I am sending two sheets of the horizontal force record, Fig. 1, the one, A_1, covering the interval October 29, 10.40 a.m., to October 31, 10.16 a.m., the other, A_2, October 31, 10.21 a.m., to November 1, 10.42 a.m. On October 31 some of the trace is off the sheet about 10 a.m., also between 2 and 4 p.m. and between 5 and 7 p.m. The time or base line answers to an arbitrary value (determined by the absolute observations), and 1 cm. of ordinate in the original curve represents 50γ (where $1\gamma = 1 \times 10^{-5}$ C.G.S.), increasing ordinate representing increasing force.

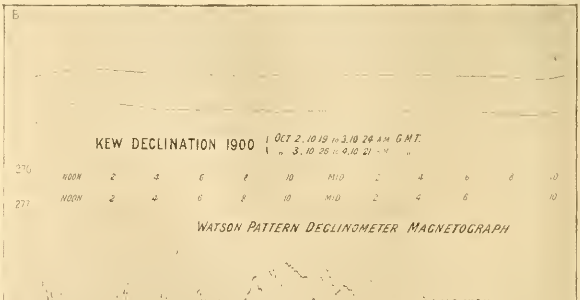

FIG. 2.—Reduced Registers of Declination.

I also send a copy of part of the declination record, B_2, Fig. 2, given by a Watson pattern magnetograph made by the Cambridge Instrument Company, sent to the Laboratory for test. The original shows, I think, all the movement, which was partly lost on our own magnetograph, the scale of ordinates of which is more open. In this curve 1 mm. represents in the original very nearly 1′ of arc, and increasing ordinate decreasing westerly declination. We had not set the clock driving this instrument quite correct, and the times shown in the trace are about four minutes wrong.

During the rapid movements the traces on the originals are faint, and consequently are not fully shown in the photographic copies sent you.

I ought to explain that the slight blurring and want of clearness on the horizontal force trace October 29–31 really arise from the electric trams. Their action, however, is hardly visible during the storm proper in either declination or horizontal force. In the vertical force, however—of which no copy is sent—the electric tram disturbance is much more considerable, and might easily be mistaken by the uninitiated for a fairly active magnetic storm.

In the accompanying illustrations, Figs. 1 and 2, 1 cm. represents practically 4 cm. of the original curves.

SUPERINTENDENT OBSERVATORY DEPARTMENT.

The National Physical Laboratory, Richmond, Surrey, November 7.

Expansion Curves.

IN your issue of October 8 Prof. John Perry describes in a letter "an exceedingly simple, ingenious method" of plotting the so-called polytropic curve representing the law pv^n = constant, which method he found in a pamphlet by Mr. E. J. Stoddard, of Detroit. I may be permitted to state that this method was published for the first time eighteen years ago by Prof. E. Brauer in the *Transactions* of the Society of German Engineers, 1885, p. 433, and since Prof. Brauer's publication this method has been used in a number of treatises on thermodynamics published in Germany and France. It has been given for years in the very valuable handbook "Huette," which is undoubtedly known to Prof.

Perry. Is it not surprising that a method which Prof. Perry himself considers very important should have to reach England from Germany by the circuitous path of the United States?

The reorganisation of technical education in England has occupied the wisest men in England for the past thirty years. It seems to be of so much importance that it has been made the subject of Sir Norman Lockyer's recent presidential address before the British Association. It seems to me that a plea might well be made for the acquisition of a reading knowledge of modern languages, especially French and German, in the advanced public schools. Prof. Perry re-discovered in an American paper, eighteen years after its first publication, a very important method for constructing a curve continually used in thermodynamics. Nineteen years ago Prof. Herrmann originated and described the entropy diagram, so often attributed to Mr. Macfarlane Gray, through whose admirable paper, read in 1889, the entropy diagram has since come into general use. There are a number of similar cases which might be cited in favour of the cultivation of a reading knowledge of those modern languages which are apt to contain valuable contributions to scientific knowledge. Forty-three years ago Prof. Huxley wrote, "What is it that constitutes and makes man what he is? What is it but his power of language—that language giving him the means of recording his experience—making every generation somewhat wiser than its predecessor—more in accordance with the established order of the universe? What is it but this power of speech, of recording experience, which enables men to be men. . . ." We might paraphrase Huxley's words and apply them to the advantage that a knowledge of the modern languages gives its owner in regard to utilising the experience of other men and nations.

B. A. BEHREND.

Station H, Norwood, Cincinnati, Ohio, October 26.

IT was of very little importance to me to find out whether the method was new; the important thing was that it was not generally known in England, that I, who read a good deal, had never seen the method, and that many of my friends who read French and German engineering books more than I do had never seen it. I may say without any contrition that there are useful things not only in French and German, but in Italian, Russian, and Chinese, as well as in English books unknown to me and to many other people, but surely this is not enough for an argument for the absolute necessity for a study of Chinese or German. Before our "advanced public schools" take up the study of French and German or Chinese, I should like to see them take up the study of English. In America and Scotland English is really well taught in many schools; this is not the case in England.

J. PERRY.

November 11.

The Leonid Shower of 1903.

QUITE an abundant and attractive display of Leonids was observed here this morning (Monday, November 16). I began to watch the north-eastern sky at midnight (following November 15), and found meteors increasingly numerous. After 2 a.m. November 16, the numbers appearing in alternate intervals of fifteen minutes were as follows:—

	h.	m.		h.	m.		Leonids
Nov. 16 ...	2	0	to	2	15	a.m.	10
	2	30	to	2	45	,, ...	14
	3	0	to	3	15	,, ...	13
	3	30	to	3	45	,, ...	13
	4	0	to	4	15	,, ...	26
	4	30	to	4	45	,, ...	34
	5	0	to	5	15	,, ...	28
	5	30	to	5	45	,, ...	42
	6	0	to	6	15	,, ...	21

The horary rate of apparition for one observer was approximately as under:—

		Leonids
0 to	1 a.m.	16
1 to	2 ,, ...	20
2 to	3 ,, ...	48
3 to	4 ,, ...	52
4 to	5 ,, ...	120
5 to	6 ,, ...	140

Maximum 5h. 30m. to 5h. 45m. a.m., when the rate was nearly three per minute.

The position of the radiant point was at $151^\circ + 22^\circ$, and it formed an area about 6 degrees in diameter. The great majority of the meteors, however, diverged accurately from the central part of the area.

During the minute following 3h. 44m. a.m. five Leonids appeared.

The meteors generally were very bright, and comparatively few were seen fainter than second magnitude. The more conspicuous objects were as follow:—

Nov. 16 a.m. h. m.	Mag.	From α °	δ °	To α °	δ °
0 36 ...	1	... 122 +	$24\frac{1}{2}$ ...	103 +	$23\frac{1}{2}$
1 13 ...	1	... $119\frac{1}{2}$	48 ...	97	$53\frac{1}{2}$
2 36 ...	Sirius ..	$117\frac{1}{2}$	$26\frac{1}{2}$ ...	98	$26\frac{1}{4}$
2 43 ...	1	... 162	$38\frac{1}{2}$ ...	168	44
2 44 ...	♃	... 73	$72\frac{1}{2}$ ...	17	63
4 4 ...	1	... $168\frac{1}{2}$	37 ...	186	45
4 12 ...	♃	.. 70	70 ...	19	59
4 37 ...	♃	... 138	35 ...	133	39
4 45 ...	♃	... 92	53 ...	68	$52\frac{1}{2}$
4 45 ...	♀	... 138	12 ...	134	$7\frac{1}{2}$
5 11 ...	1	... 213	29 ...	223	27
5 14 ...	♃	... 173	$40\frac{1}{2}$ ..	190	47
6 5 ...	♃	... 182	51 ...	195	$55\frac{1}{2}$

A few meteors were noticed from minor showers, two particularly interesting objects being:—

a.m. h. m.					
3 41 ...	4	... 219 +	63° ...	209° +	$61\frac{1}{4}$°
3 59 ...	2	... 178	19 ...	223	41

These moved very slowly, and probably belonged to radiants at $262^\circ + 62^\circ$ and $147^\circ - 11^\circ$ respectively.

I should be glad to hear of duplicate observations of any of the above, as it is desirable to compute their real paths if the necessary materials can be obtained.

Bristol, November 16. W. F. DENNING.

Autophyllogeny in the Vine (Vitis).

I LATELY received from a neighbour a vine-leaf, taken from his own garden, exhibiting the uncommon phenomenon known as "autophyllogeny." A small green leaf had arisen from the midrib, near the apex of the central lobe, upon the upper surface of the leaf. The supernumerary leaf was sessile, and had its upper surface turned towards the corresponding surface of the primary leaf, in the same direction of growth. The leaflet appeared to be of the normal shape, but, owing to a slight malformation, it was not fully expanded, and I could not therefore entirely satisfy myself upon this point.

Dr. Masters, in his "Vegetable Teratology," cites instances in which supernumerary leaflets have been observed upon the upper surfaces of leaves of Heterocentron and Miconia, and upon the under surfaces of leaves of other plants, but I cannot find any record of their occurrence in the vine.

HERBERT CAMPION.

Walthamstow, Essex.

The "Dew-bow."

ON Wednesday and Thursday, November 4 and 5, fogs prevailed in this district and brought by mild winds great quantities of carbonaceous dust from over the town, which covered the surface of the top pond in Vernon Park with a dry film. On the morning of Friday, November 6, hoar frost covered the grass and walks; the film of dust on the pond was covered with a glistening coat of minute watery globules. At 11.20, standing with my back to the sun, I noticed a bright streak of light on the surface of the water, and on moving a few feet further saw that it was split up into the colours of the prismatic spectrum, and presented the appearance of the rainbow, as it appeared curved. There were two spectra, one fainter than the other. The phenomenon was visible for more than four hours, and I directed the attention of several gentlemen to it. In November, 1885, Mr. Thomas Kay, Moorfield, Stockport, saw a similar phenomenon on Lake Windermere, and pub-

lished the observation. The things necessary to produce it appear to be:—(1) a dry film of dust on surface of water; (2) a layer of fine globules of moisture on the film; (3) a dead calm, that the globules be not shaken into coalescence; (4) the sun shining brightly at a low angle through a clear atmosphere. EDWARD HEWITT.

Municipal Museum, Vernon Park, Stockport, November 11.

Weather Changes and the Appearance of Scum on Ponds.

IF the scum referred to (NATURE, November 5, p. 7) be organic in character—algal, for instance—it would contain bubbles of gases.

Would not these bubbles tend to enlarge, from the expansion of their contained gases, on a lowering of barometric pressure, and the mass, becoming specifically lighter, to rise?

"Platanus orientalis" says "any decided change of weather." The above explanation would hold good only for a change of weather indicated by a falling barometer. H. J. GLOVER.

Stationers' School, Hornsey, N., November 6.

Earthquake at Kashmir.

IT may perhaps be of interest to note (I do not find the fact recorded in NATURE) that on April 18, 1902, there was a sharp earthquake shock over North-west India and Kashmir, about 2.30 a.m. (local time). O. ECKENSTEIN.

34 Greencroft Gardens, London, N.W., November 13.

A NEW THEORY OF THE SOIL.[1]

IT has long been recognised that the chemical composition of the soil affords a very imperfect index to its fertility, partly due to the fact that only recently have methods of analysis been devised to discriminate between the total plant food in the soil and that which is active and likely to be immediately available for the plant, but chiefly because the physical texture of the soil and its power of maintaining a supply of water to the growing plant is a much larger factor in crop production than its store of nutrient material.

But though the part played by the chemistry of the soil has doubtless been much exaggerated and requires to be studied more in connection with soil physics, it has been reserved for the chemists of the United States Bureau of Soils to deny its action entirely, and put forward a theory which considers all soils to be effectively the same from the chemical standpoint.

Briefly stated, the thesis developed in the *Bulletin* before us is as follows:—dissatisfied with the want of correspondence between the results of any of the methods of soil analysis in which the soil is attacked by either weak or strong acids, Dr. Whitney and his associates have fallen back on the aqueous solution obtained by shaking 100 grams of the soil with 500 c.c. of water and allowing it to stand for twenty minutes. For the rapid quantitative examination of the very weak solution thus resulting they have worked out various colorimetric methods, and in this way have been able to analyse several hundred soils of the behaviour of which in the field something was known.

From these results the authors come to the conclusion "that with occasional exceptions the composition of the soil solution and the concentration is about the same in all cultivable soils." "All our principal soil types, in fact, practically all cultivable soils, contain naturally a nutrient solution which varies within comparatively narrow limits with regard either to composition or concentration, and which is usually sufficient for plant growth. Apparently, therefore, all soils are amply supplied with the necessary mineral plant foods, and these plant foods are not in themselves a matter of such paramount importance to the agriculturist, for their supply as regards the plant is determined by the supply of soil moisture which the crop can obtain from the soil." The authors further suggest that fertilisers, if they have any effect in increasing the crop, do so in the main by altering the physical texture of the soil or by stimulating the root range of the plant. So novel a point of view from men with the experience of Dr. Whitney and his colleagues demands a careful consideration of the evidence in its support.

On the theoretical side the authors suggest that in the natural soil solution on which plants feed "the quantity of any constituent which can possibly enter the solution is . . . determined by definite equilibrium conditions with the but slightly soluble mineral from which it is derived . . . it may very well happen that the addition of comparatively small amounts of a readily soluble potassium salt to a soil would simply force back the dissociation and solubility of the potash minerals with no consequent gain of potassium to the soil solution." In support of this view the authors describe an experiment in which powdered potash felspar when shaken up with water is shown to yield a feebly alkaline solution, as indicated by phenolphthalein. On adding, however, a little soluble potassium salt the colour of the phenolphthalein is partly discharged, which the authors consider to indicate that some of the potash derived from the felspar has been forced back to the solid phase. We would suggest the consideration of another experiment; take a very weak solution of potassium phosphate, add a drop of phenolphthalein solution, and run in dilute alkali until a distinct colour appears; now add a little solution of some neutral salt, sodium or potassium chloride; the colour will again be partially discharged, although the salt added is strictly neutral.

In the latter experiment there is no question of the intervention of a solid phase; both experiments are, we think, equally explicable on the dissociation hypothesis, but the one does not bear the interpretation put on it by the American chemists.

Turning now to the analytical figures, we cannot agree that, except in a very general and average sense, they support the authors' case that the composition and concentration of the soil solution are about the same for all soils. Taking first of all the determinations of nitric acid, they are seen to vary within the widest limits, as is evident from the following summary of the results for four of the soils:—

	No. of analyses	Nitric acid. Parts per million of dry soil		Mean
		Highest	Lowest	
Windsor Sand ...	34	26·62	0·56	5·69
Norfolk Sand ...	98	23·76	0·67	3·81
Leonardtown Loam	62	62·00	trace	12·71
Sassafras Loam ...	80	38·40	0·50	7·79

Furthermore, if the number of the determinations falling within successive equal limits be plotted into a curve, the resulting figure is highly irregular, and shows nothing of the maximum about the mean which characterises the curve of error. The nitric acid figures are thus entirely opposed to the authors' thesis; they show no tendency to a constant value, but extreme accidental variations, *i.e.* due to factors independent of the classification here adopted. But in fact too

[1] "The Chemistry of the Soil as related to Crop Production." By M. Whitney and F. K. Cameron. U.S. Department of Agriculture, Bureau of Soils, No. 22. Pp. 71. (Washington, 1903.)

much is known of the origin of the nitrates in the soil from the results obtained by Warington at Rothamsted and by King in Wisconsin to allow one to suppose their amount would ever approximate to a constant even for the same soil, yet nitrates are perhaps the dominant factor in plant nutrition.

The phosphoric acid and potash figures are a little more in harmony, and we have examined those relating to the same four soils with the following results:—

	Phosphoric acid. Parts per million		
	Highest	Lowest	Mean
Windsor Sand	12·88	2·65	6·21 ± 0·25
Norfolk Sand	16·52	1·71	6·33 ± 0·19
Leonardtown Loam ...	16·5	2·9	7·16 ± 0·26
Sassafras Loam	21·45	2·24	7·61 ± 0·30

	Potassium. Parts per million		
	Highest	Lowest	Mean
Windsor Sand	46·11	10·90	24·27 ± 1·02
Norfolk Sand	44·9	11·64	22·19 ± 0·49
Leonardtown Loam ...	51·66	10·08	23·61 ± 0·65
Sassafras Loam	46·8	7·94	24·22 ± 0·63

These numbers would indicate variation round a mean which is practically the same for all soils as regards potash, but which as regards phosphoric acid has a different value for different types of soil, approaching one value for sands and another for loams. This agrees with the probability that the potash compounds are of the same type in all soils, whereas several distinct compounds of phosphoric acid must exist in relative proportions varying with the type of soil, and we surmise that these mean results might be correlated with the amount and solubility of the compounds appropriate to the various types of soil were more data available. But for the purpose of the argument we are not concerned with mean results, but with individual soils; the authors rest their case on the constancy of composition of the soil solution, and their own figures show variations too wide and too numerous to fall within any allowable limits. It may be true enough that the variations exhibited cannot be correlated with the known productiveness of the soils, but that is only a proof of the ineffectiveness of the analysis of the aqueous extract of a soil, not of the non-existence of a chemical soil factor in crop production. Indeed, it is not quite easy to see what the numbers do represent; the volume of water employed is so small, and the time of extraction so short, that they cannot stand either for the solution existing in the soil or for the material which water could extract during the growth of a crop. Some analyses are given of the actual solution extracted from various soils; all that can be said of them here is that they show no more constancy of composition than the laboratory extracts, nor do the old analyses of the drainage waters at Rothamsted lend any more support to the idea of a soil solution of constant composition.

Though Dr. Whitney's main argument is thus hardly tenable on his own showing, certain side issues are worth a little notice. Dealing with the action of fertilisers, he notices that, while the wheat crop on the best fertilised plot at Rothamsted averages about 33 bushels, on the plot which has been unmanured for sixty years it has fallen to 12 or 13 bushels. Yet on the similarly unmanured plot in the Agdell field, where the wheat is grown once every four years in rotation with roots, barley, and clover or fallow, but little falling off is apparent. Hence he concludes that, in virtue of the rotation, the fertility of the Agdell field is unimpaired, whereas in the continuous wheat field "the decrease can be ascribed only to some physical change in the soil, to some chemical change other than the actual loss of plant food taken up by the crops." But when any other crop on the unmanured plots in Agdell field is considered, the decline in fertility is enormous; roots and clover only yield minimal crops; so far as they are concerned the cultivation of the soil involved in the rotation has been quite unable to maintain the fertility. The wheat, with its powerful root system, holds up better, but its production is falling steadily; it is important to see how long it will be maintained, though it need never be expected to fall to the level of the continuous wheat, because the land is practically only cropped every other year, so trifling has the output of roots become.

When Dr. Whitney says that there are few instances showing that a given fertiliser is required by a certain soil, and that generally fertilisers have no consistent or continuous effect, he ignores too much the results both of experiment and experience in countries like our own. In England a body of knowledge has been accumulated concerning the requirements of particular soils and crops for specific fertilisers such as is hardly possible in America, where much of the land has only recently been brought under intensive cultivation involving the use of purchased manures.

In another place Dr. Whitney says "the beneficial effect of fallowing is not due to an accumulation of soluble plant food in the soil." Not wholly due, perhaps, but King's investigations show what a powerful factor the accumulated nitrates become, and a recent discussion of the Rothamsted results shows that after a wet autumn, to wash out the nitrates formed during the summer fallow, the benefit of fallowing disappears almost entirely, whereas after a dry autumn and early winter it produces an increase of crop of nearly 50 per cent.

Suggestive as Dr. Whitney's memoir must be to all agricultural chemists, we thus do not consider that the main theory it propounds possesses any permanent value. We should be sorry if we have failed to appreciate the argument properly, but it is not always easy to follow, the text being somewhat deficient in sequence and orderly arrangement; indeed, we are disposed to think that had the question been set out a little more nakedly at the outset, and the demonstration marshalled with more precision, a somewhat different conclusion would have been reached by the authors. The fundamental thesis is unimpeachable, that water content and temperature are the main factors in crop production, but the chemical composition of the soil is also a large factor, though its magnitude and relation to the other physical factors do not yet admit of complete determination.

A. D. H.

THE SURVEY OF INDIA.

A VOLUME of extracts from narrative reports of the Survey of India for the season 1900–1901 [1] has recently been issued. These extracts, which used to be published in the same volume as the annual report, are now issued separately. The reports selected for publication show admirably the range of the operations of the Survey of India. They deal with seven subjects.

(1) *Zincography*.—For certain classes of maps reproduction from zinc is eminently suitable, and owing to the introduction of thin zinc plates, difficulties of

[1] Pp. 68. (Calcutta: Government Printing Office, 1903.) Price 2s. 3d.

storage have largely disappeared. For the rapid reproduction of maps photozincography was, until a few years ago, the method invariably used. Two new methods have now superseded photozincography; one of these, "heliozincography," was worked out by the Ordnance Survey, and subsequently adopted by the Survey of India; the other, the "Vandyke process," was invented by Mr. Vandyke, of the Survey of India, and has now been adopted by the Ordnance Survey. The first method consists in reproduction direct on a sensitised zinc plate in contact with a reversed negative. The Vandyke process consists in reproduction direct on a sensitised zinc plate in contact with the original drawing. Lately, at Southampton, it has been even found possible to reproduce maps drawn on thick drawing paper. The process has been patented by Mr. Vandyke, and is a cheap and very efficient means of reproducing cadastral maps.

(2) *Geodetic Triangulation in Burma.*—The principal point to note is the determination of the coefficient of terrestrial refraction by night as well as by day, the coefficient being the absolute refraction divided by the terrestrial arc. By day (from observations to heliostats between noon and 3 p.m.), the coefficient was 0·072; by night (from observations to lamps), 0·083. It is possible that if the night observations had been taken from midnight onwards the coefficient would have been smaller.

Some interesting secondary triangulation (the Manipur series) was also carried out, one of the rays being 95 miles long.

(3) *Latitude Operations.* The average probable error of 14 latitudes observed with a zenith telescope was $\pm 0''.063$, or say six and a half feet. India is, of course, committed to the system of refined latitudes, and comparatively few of them.

(4) *Experiments with the Jäderin Base Apparatus.*—A base was measured at Dehra Dun with the following results:—

By Jäderin apparatus...	...	39,187·272 feet
By Colby's bars ...	...	39,187·462 ,,

a discrepancy of 1/194,000.

It was found that the 80 ft. wire was the most convenient, and various practical suggestions are made on the use of the apparatus. It was apparently in contemplation to measure a Jäderin base in Burma. There would appear to be no doubt as to the gain in speed, and also no doubt that it is possible under suitable conditions to do away with base-line figures by the use of, say, 15 mile bases.

(5) *Magnetic Survey of India.*—This has been commenced, and there are now five base stations, Calcutta, Bombay, Rangoon, Dehra Dun, and Kodaikanal. It was intended in 1901 to send out three field detachments to work in an area west of a line joining Dehra Dun and Bombay, two to work along railway lines, and a third in the desert.

(6) *Tidal and Levelling Operations.*—Tidal observations have been, or are being, taken at forty-one ports in, and adjacent to, the Indian Empire. Tables are given of the tidal constants at various ports deduced from the 1900 observations. As regards the accuracy of prediction, at fourteen open coast stations during 1900 it was found that the mean error of prediction of the time of high or low water was thirteen minutes, and the average error of predicted heights was one twenty-fifth of the range.

The tide-predicting machine belonging to the Indian Government (due, it is believed, to Lord Kelvin and Mr. Roberts) is in London, and the Survey of India sends home annually the latest values of the tidal constants to Mr. Roberts, who sets the instrument for the port in question, and causes it to describe graphically the tide curve for any future year required. As Prof. Darwin has remarked in his book on "The Tides," it is characteristic of England that this admirable machine has not been made use of for any of the home ports.

(7) *Topographical Surveys.*—The seventh report deals with some details of one-inch work in Burma, and incidentally serves to emphasise the necessity of keeping cadastral and topographical work distinct. The topographical surveys are fully described in the annual report, the most interesting being the survey on a scale of half inch to one mile of 17,000 square miles carried out in China during the expedition.

When shall we have an Imperial Survey capable o' doing for the Crown colonies, protectorates and occupied territories what the Survey of India does for India?

C. F. C.

ISAAC COOKE THOMPSON.

Liverpool has lost a well-known naturalist in the death of Mr. I. C. Thompson, who was hon. treasurer of the Liverpool Marine Biology Committee from its foundation nearly twenty years ago. He had a wide knowledge of the Crustacea, and especially of Copepoda, the group upon which most of his original work was done, but he was also a keen field-naturalist, interested in the lives and habits of his animals, and preferring to catch the specimens himself and to examine them in the first place alive. He was always a prominent member of the party during the dredging expeditions in the Irish Sea and at the Port Erin Biological Station. Little more than a month before his death he was one of the leaders in the British Association dredging excursion which followed the Southport meeting.

Thompson's early papers on the Copepoda dealt with the forms found in Liverpool Bay and other parts of the Irish Sea, but he collected wherever he went, and, as the result of vacation travels, published papers on the Mediterranean and Norwegian species and on collections from Madeira, the Canaries, the west coast of Ireland, the Færöe Channel, and a traverse through the North Atlantic to Quebec. He also described Copepoda from the Bay of Bengal, the Antarctic, the Red Sea and east coast of Africa, and recently from the *Oceana* Expedition in the North Atlantic. In these papers he described many new forms, aided in the elucidation of not a few obscure points, and greatly extended our knowledge of the geographical distribution of the group. Thompson's last piece of scientific work was a large report, undertaken jointly with Mr. Andrew Scott, upon the Copepoda of the Ceylon pearl banks, recording more than 280 species, of which 76 are described as new to science. This extensive work was completed some weeks ago, and Thompson passed the last of his sheets for press shortly before he was struck down; it has been referred to by one who saw the proofs as the pioneer work on tropical Harpacticidæ and Lichomolgidæ. Thompson's papers have been published for the most part in the *Transactions* of the Liverpool Biological Society, the *Journal* of the Linnean Society, the *Annals and Magazine of Natural History*, and the reports of the British Association. He was in correspondence with Claus, Richard, Giesbrecht, and other Continental workers, and frequently supplied them with British specimens required for comparison or description in their monographs.

There were few of the local organisations in Liverpool for the advancement of science and the applications of scientific teaching in which Mr. Isaac Thompson did not play a prominent part, and his posi-

tion, even twenty years ago, was fitly indicated by his selection, in April, 1882, to attend Darwin's funeral in Westminster Abbey as the representative of the Liverpool scientific societies. On the occasion of the last visit of the British Association to Liverpool, in 1896, Thompson was one of the local secretaries, and his colleagues can testify how well he did his share of the hard work, and how much the success of that large meeting depended upon his admirable business arrangements and careful attention to detail. He was a fellow of the Linnean Society and a regular and active member of Section D at British Association meetings. He was one of the founders of the Liverpool Biological Society and the L.M.B.C., and it was in connection with the latter, and during the last fifteen years, that most of his original scientific work was done.

Isaac Thompson was a good example of the serious amateur who does sound systematic work and makes lasting contributions to science. His loss will be keenly felt, not only in Liverpool, but by the large number of scientific men throughout the country who were his personal friends. We all admired his sterling, upright character and his sympathetic loving nature.

W. A. H.

NOTES.

Prof. J. H. van 't Hoff and Dr. Robert Koch have been elected honorary members of the Vienna Academy of Sciences. Sir William Ramsay, Prof. G. B. von Neumayer, Prof. H. Poincaré, Prof. E. J. Marey, and Prof. K. Golgi have been elected foreign correspondents of the same Academy.

The death is announced of Prof. Robert H. Thurston, of Cornell University, at the age of sixty-four. From 1866 to 1871 Prof. Thurston occupied the chair of natural philosophy at the United States Naval Academy. Subsequently he became professor of engineering at Stevens Institute, where he remained until he proceeded to Cornell, in 1885, as professor of mechanical technology.

Dr. Einar Lönnberg has been appointed director of the zoological department of the Museum of Gothenburg.

Reuter reports that two earthquake shocks were felt at Shuraz, Persia, on the night of November 14.

Mr. W. J. Palmer, a graduate of the Ontario Agricultural College, has been appointed director of agriculture in the Orange River Colony at a salary of 1200*l.* per annum.

The sixth International Congress of Applied Chemistry is to be held at Rome in 1906. Prof. E. Paterno, of Rome, has been elected president of the organising committee.

It is stated by *La Nature* that the body of a Tyrolese guide who fell into a crevasse on the glacier of Gross-venediger, in the Austrian Alps, thirty years ago, has been found in a remarkable state of preservation at the foot of the glacier.

A monument to the brothers Haüy was unveiled at their birthplace, Saint-Just-en-Chaussée (Oise), on November 8. The elder brother, René Just Haüy, who died in 1822, was the eminent mineralogist. The ceremony was presided over by M. Edmond Perrier.

At a meeting of the Royal Statistical Society held on Tuesday, the president, Major P. G. Craigie, C.B., delivered his opening address. Before doing so he presented, on behalf of the council and the society, a Guy medal in silver to M. Yves Guyot, for his paper on "The Sugar Industry of the Continent," which was read before the society on May 29, 1902.

The Craggs research prize, for the best piece of original work done during the current year by present or past students of the London School of Tropical Medicine, has been awarded to Dr. Aldo Castellani for his researches into the etiology of sleeping sickness. Dr. Travers has been awarded honourable mention for his paper "Beri-Beri."

Commander Peary was, on November 12, in Edinburgh, presented with the Royal Scottish Geographical Society's Livingstone gold medal. Previous awards of the medal were to Sir Harry Johnston for discoveries in Africa, and to Dr. Sven Hedin for exploration in the central region of the Ural-Asian continent.

Mr. M. H. Maw, of Walk House, Barrow-on-Humber, states that the radiant point of meteors seen by him in the early hours of Monday seemed to be about ten degrees south of the zenith. Meteors under the Pole Star seemed to move vertically down through 30° in about half a second. Taking the altitude of such a meteor to be eighty miles, the length of the arc described in half a second would be forty-two miles if the motion were at right angles to the line of sight.

A Reuter telegram from Rome reports that experiments made by the Italian naval authorities with a new system of radio-telegraphy originated by Prof. Alessandro Artom have conclusively proved that the new system enables electric waves to be transmitted in a given direction. The Minister of Marine has instructed Lieutenant Pullino, director of the wireless telegraph station of Monte Mario (Rome), to give every assistance in further experiments with the Artom system.

The *Times* reports that the expedition to Tibet, under Captain Rawling and Lieutenant Hargreaves, of the Somerset Light Infantry, which left Leh in Ladak last May, arrived in Kashmir territory on October 4. Triangulation was extended as far as longitude 85° E., the highest latitude being 35° 45′, and lowest 32° 45′. Many new lakes were discovered, the largest having an area of 70 square miles. One hundred points were fixed by triangulation, and latitudes of all the camps by astronomical observations; 38,000 square miles of country were surveyed.

The following prizes have been awarded by the council of the Royal Society of Edinburgh:—(1) the Keith prize for 1899–1901 to Dr. Hugh Marshall for his discovery of the persulphates, and for his communications on the properties and reactions of these salts, published in the *Proceedings* of the Society; (2) the Makdougall-Brisbane prize for 1900–1902 to Dr. Arthur T. Masterman for his paper entitled "The Early Development of *Cribrella oculata* (Forbes), with remarks on Echinoderm Development," printed in vol. xl. of the *Transactions* of the Society. The prizes will be presented at the meeting of the Society on December 7.

A correspondent of the *Times* reports that on November 12 a balloon belonging to MM. Lebaudy, and called *Le Jaune*, started from Moisson, about 55 kilometres from Paris, at 9.10 a.m., arrived at the Eiffel Tower at 10.50 a.m., and effected its descent on the Champ de Mars. According to M. Juchmès, an aëronaut and one of two passengers, the balloon encountered at first a south-south-west wind travelling at the rate of six metres a second. Almost the whole way he had to keep the point of the balloon somewhat to the right of the direction he intended to take. The maximum altitude attained was 300 metres, but the average was about 100.

Announcement is made of the proposed publication of a new journal under the title *Archivio di Fisiologia*, edited by Prof. Giulio Fano, director of the physiological laboratory at Florence. The journal will be especially concerned with experimental work, but synthetic reviews and philosophical disquisitions will not be excluded from it. Contributions will be published, according to the wish of the author, in English, Italian, German or French. The *Archivio di Fisiologia* will appear every two months, forming a yearly volume of about 500 pages. The English agents are Messrs. W. Heffer and Sons, Cambridge.

Mr. E. Kitto, superintendent of the Falmouth Observatory, sends some particulars of the recent magnetic storm registered at that observatory. Commencing on October 31 at 7 a.m., the disturbance continued until 5 a.m. on November 1. It was severe from 7 a.m. to 7 p.m. on October 31, but the period of exceptional severity was between 1 p.m. and 7 p.m., during which time the declination magnet swung through an arc of 2 degrees 2 minutes, as determined by actual measurements of the declination curve. The Falmouth Observatory magnetic records are continuous from January, 1887, but the magnetic storm of October 31 stands out as the most remarkable record of magnetic disturbance ever made at the observatory.

It is reported by the *Pioneer Mail* that the Secretary of State for India has definitely sanctioned the scheme for establishing an agricultural college at Pusa, in the Muzaffarpur district. The intention is to combine a large experimental farm and an agricultural college with an institution for research, so as to form a great Imperial institution. The fine Government estate at Pusa will be the headquarters of the staff of various experts, including an agricultural chemist, who will be mainly an analyst and cryptogamic botanist, whose business it is to investigate the diseases which attack the principal indigenous crops, and an entomologist, charged with the study of insect pests. A cattle farm for the improvement of the local breed of cattle will also be included.

A lectureship has been endowed in the University of Birmingham by an anonymous friend in memory of the late Prof. Huxley. We learn from the *British Medical Journal* that the lecture is to be given annually, either in the winter or spring terms, and to be open to all members of the university without payment. It is to be called the Huxley lecture, and for its endowment a sum of 20*l.* per annum has been given. The lecture will also commemorate the opening of Mason's College, the predecessor of the university, by Prof. Huxley. As the donor has expressed a wish that the first lecture should be given by someone who knew the late Prof. Huxley intimately, and who was associated with his work, it has been decided by the council on the recommendation of the Senate to invite Sir Michael Foster, K.C.B., F.R.S., to deliver the first lecture.

On the completion of the portrait of the late Prof. P. G. Tait for the Hall of Peterhouse, Cambridge, the treasurer was able to announce a surplus in hand. It was therefore suggested that an attempt should be made to increase this amount until it should suffice for the establishment in the college of a prize associated with Prof. Tait's name, and to be given for excellence in his subject, physics. Mention was made of this project in our issue of October 22 (p. 603); and we now learn that a final report made to the master and fellows of Peterhouse on October 29 showed that the amount of the fund had reached the substantial total of 200*l.* A committee was appointed to draw up regulations for the award of the prize, and record was made of the gratitude of the college to all who have united in establishing this worthy memorial of a renowned *alumnus* of Peterhouse.

Mr. R. Kaye Gray, in his presidential address to the Institution of Electrical Engineers last Thursday, dealt with a number of subjects of importance and interest. He referred at some length to the development of electric traction and power-supply in this country, and laid considerable stress on the difficulties caused by faulty legislation, which had hampered the progress of these branches, and, indeed, to a certain extent, of all electrical engineering in England. All engineers will join in his hope that the Government will speedily carry out the promises made to the deputation headed by Mr. Swinburne last year, and will both introduce and carry through really effective amending measures. Mr. Gray referred to the fact that the Institution had recently purchased a site for building a permanent home for itself, and said that there was no intention of building as yet, partly because it was possible that in the near future the various engineering interests might unite to build "one large temple of engineering," in which all might find a home.

For several years past valuable statistics of rainfall and other meteorological phenomena recorded at Zomba, in British Central Africa, have been published by the scientific department of that protectorate; the head of that department is Mr. J. McClounie. We are somewhat surprised to find that, as the head of a public department, he has ventured to depart from the orthodox scientific methods adopted by official meteorologists, and has issued daily rainfall forecasts from June 1903 to May 1904, and estimated monthly amounts for various parts of Nyasaland. He states that "the forecasts have been framed according to the relative positions of the moon and the sun on the dates noted, and the estimates formed according to the various movements of the moon, and proportionate to our knowledge of the average rainfall of each month as regulated by latitude and altitude." Prof. Pernter, in the paper referred to in our issue of last week, has pointed out, as, indeed, Herschel stated many years ago, that the influence of the moon on weather is so small as to be almost inappreciable. We are not prepared, without further inquiry, to endorse Prof. Pernter's opinion that the adherents of the lunar theory carefully note the days on which their forecasts have been successful, but take no heed of the failures; we are, however, not yet prepared to admit that this method of forecasting weather is likely to lead to any useful results.

Some further particulars with regard to the alleged discovery of the cancer parasite by Dr. Schmidt (see Nature, November 12, p. 34) are published in the *Lancet*. These are given by Mr. H. J. Johnson in a paper read before the Abernethian Society at St. Bartholomew's Hospital. Dr. Schmidt claims not only to have isolated the parasite, but to have cultivated it, though no details are given. By the use of killed cultures a vaccine is prepared, the injection of which into a patient with cancer is stated to be followed by a reaction and by curative effects. By injecting animals with the cultures, their serum acquires antidotal properties, and may also be used for treatment. At present there is no supply either of the vaccine or serum available for treatment.

In a recent number of Nature (vol. lxviii. p. 8) a brief summary was given of the position of the present epoch in relation to Brückner's long weather cycle of 35 years, and it was there shown that as regards the total rainfall of the British Isles we have now passed a minimum or "droughty period," and are commencing a wet cycle, which will reach

a maximum about the year 1913. Mr. Douglas Archibald, in a letter to the *Times* for November 16, gives some figures which represent the variation of the rainfall over the London area from the year 1813, using Greenwich and Mr. Dines's observations. Arranging these 90 years in groups as suggested previously by Brückner, he gives an interesting table showing not only the excess or defect of rain, but also the excess or defect of atmospheric pressure and the variations of the price of wheat since 1856.

Group of years assigned by Brückner	Character of the Period	Total excess or defect of rainfall in the period	Total excess or defect of barometric pressure, Greenwich	Mean annual fluctuations of yield of wheat from the true average over the United Kingdom
		Inches	Inches	Bushels
1806–25	Wet	+15·54 [1]	−0·065 [1]	
1826–40	Dry	− 6·17	+0·165	
1841–55	Wet	+ 4·35	−0·045	
1856–70	Dry	−11·85	+0·150	+1·7
1871–85	Wet	+19·65	−0·120	−2·0
1886–1902	Dry	−29·75	+0·272	+2·2
1903–1920(?)	Wet	—	—	—

[1] 1813 to 1825 for both.

Mr. Archibald concludes his letter by saying that "we are apparently entering upon a period of more than average rainfall, less than average barometric pressure, and about two bushels less than the average wheat yield per acre."

Messrs. W. J. McNeal and F. G. Novy report that they have succeeded in cultivating the trypanosome parasite of the rat, *T. Lewisi*, in a mixture of sterile defibrinated rabbit's blood and ordinary nutrient agar. Ordinary nutrient agar is prepared, sterilised, and allowed to cool to 50° C. One-third of its volume of defibrinated rabbit's blood, obtained with aseptic precautions, is then added, and the test-tubes containing the mixture are allowed to solidify in the oblique position. Loopfuls of rat's blood containing the parasite are then sown into the condensation water at the bottom of the tubes. In this the trypanosomes readily develop at 34–37° C. During a year eleven passages were made from tube to tube, and a small quantity of the culture from the tenth tube readily infected a rat inoculated with it (ref. in *Bull. de l'Inst. Pasteur*, i., No. 16, p. 602).

The current number of the *Journal of the Sanitary Institute* (October) is mainly devoted to the papers read at the congress at Bradford and the discussions thereon. Several papers deal with the question of sewage disposal and with the bacterial systems of sewage disposal, the standardising of sewage being the subject of a joint discussion in the engineering and biological sections. The "Standardisation of Disinfectants" is the title of a paper by Messrs. Rideal and Ainslie Walker, and it is proposed to test all disinfectants under the same conditions of time, &c., and to compare the results with those obtained with carbolic acid solution. Thus if a 1 in 70 solution of disinfectant X possessed the same disinfecting action as a 1 in 80 solution of carbolic acid, the efficiency of disinfectant X compared with carbolic acid would be $70/80 = 0.87$. This is termed the carbolic acid coefficient.

A report has been issued by Prof. K. R. Koch dealing with the gravitational measurements conducted under the auspices of the Württemberg Geodetical Commission at ten stations on the line from Ulm to Freudenstadt. In these experiments a new pendulum made of Delta metal has been used with satisfactory results.

In a short paper reprinted from the *Rivista di Fisica* (Pavia), Ingegnere G. Zanotti Bianco deals with the history of determinations of the earth's mean density, with especial reference to the investigations of several Italian writers whose work has received but little attention, at any rate in this country. Among them are C. I. Giulio, Menabrea, and Saigey.

Mr. A. Cancani has published a paper reprinted from the *Atti dell' Accademia Gioenia* (Catania) dealing with the relation between the temperatures of springs and those of the air. A noteworthy feature of this paper is the bibliography of the subject. The principal previous bibliography was published by the Weather Bureau at Washington in 1899, and as only a limited number of copies were lithographed, it is probable that the present enlarged list will be of much use for purposes of reference.

The problem of correlation in hyperspaces forms the subject of an important paper by Mr. Giovanni Zeno Giambelli in the *Memorie* of the Lombardy Institution of Sciences and Letters. The author refers to the work of Hirst, Sturm, Visalli and others on correlation in plane and ordinary spaces. In regard to correlation in hyperspaces, the fundamental formulæ were published without proof by Schubert in 1890, and again in 1894–5. Mr. Giambelli now gives proofs of Schubert's formulæ, and obtains others of a more general character. The results are obtained by the method of "degeneration" introduced by Schubert in dealing with ordinary space and with quadrics in hyperspaces.

Papers by Messrs. Epsteen and Shaw in the last two numbers of the *Transactions* of the American Mathematical Society deal with the interesting subject of linear algebras, and bear witness to the value and originality of Peirce's researches. Another noticeable paper, in the July number, is that of Van Vleck on continued functions, on the lines of Stieltjes's memoir of 1894. The October number of the *Annals of Mathematics* contains the first part of a paper by Prof. Greenhill on the mathematical theory of the top, and a contribution by Mr. E. B. Wilson which deals with a generalised definition of area which does not involve the conception of length.

The September issue of *Annotationes Zoologicae Japonenses* deals solely with Japanese invertebrates. Mr. E. Klocke records the occurrence of the crustacean genus Bosminopsis in Japan; Mr. A. Izuka describes a new polygordian worm, while Mr. E. Ikeda treats of the development of the sexual organs in the phoronis larva.

In the *Morphologisches Jahrbuch* (vol. xxxi., part iv.), Dr. H. Fleischmann's essay on the morphology of the head-skeleton of the Amniota is continued, Dr. A. Beecker contributing a section on the nasal region in reptiles, birds, and mammals. Mr. G. Tornier describes numerous instances of the development of supernumerary digits in the fore-feet of members of the deer-tribe, due, in most cases at any rate, to injury during fœtal life. None of these appear to be atavistic.

A reprint from the *Cape Times* of the report of the recent annual meeting of the Game and Trout Protection Association of the western districts of South Africa affords very satisfactory reading. The laws for the protection of big game are apparently working well, certain attempts to curtail the close season having been vetoed by the Government. In some districts it has been found advisable to have a special close season for certain kinds of game, and to include therein a few species of birds which do not properly come under that category. A large tract of country in the

Bushmanland division of Namaqualand has been created a game reserve, in which it is unlawful to kill, hunt, or trap any description of game animal. Despite the Boer war, certain species of antelope, which have long been on the verge of extermination, still survive. Blesbok, for instance, are stated to be represented by about 650 head in the Steynsburg division, and bontebok by some 250 in Bredasdorp and 25 in Swellendam. Reedbuck include about 200 head in Komgha, where they are specially protected, and 50 in Kimberley. Nothing is, however, said with regard to the white-tailed gnu, which has been reported extinct, the "wildbeest" referred to being apparently the brindled gnu. Of zebra about 340 individuals survive, mostly in Cradock, George, Oudtshoorn, and Uniondale.

WE have on our table two parts (vol. lxxv., i. and ii.) of the *Zeitschrift fur wissenschaftliche Zoologie*, from among the contents of which a few articles are selected for brief mention. In the first part the light-organs of the glow-worm receive attention at the hands of Mr. J. Bongardt, while Mr. Haack treats of the glands in the mouth of the lampreys. In the second part Dr. E. Rohde continues the account of his important investigations into the structure of the organic cell, discussing, in this instance, the structure and mode of division of the wandering bodies known as "sphæres" and "centrosomes" which are found moving free in many cells and their nuclei. The gill-filters of fresh-water fishes form the subject of an article by Dr. E. Zander. It is shown that while carnivorous types like the pike have the inner sides of the gill-arches, the bones of the branchio-palatal apparatus, and the pharyngeals studded with minute villiform teeth, in forms like the perch, carps, and herrings there is a strongly developed sieve-like appendage ("Siebfortsätze") on both branches of the gill-arches. The fineness of this filtering arrangement is correlated with the habitat and food of the groups in which it occurs, attaining its extreme development in this respect in those subsisting on "plankton."

To the *Proceedings* of the American Academy of Arts and Sciences a list of new flowering plants obtained from Mexico and Central America is contributed by Miss J. Greenman. Most of the species belong to the Sympetalæ, so that they do not overlap with those recorded by Dr. J. N. Rose, which would be mainly included in the Archichlamydeæ.

A COMPARISON of the characters of the European and Australian Alpine floras is made by Mr. Weinsdorfer in the *Victorian Naturalist*. Flowers in the Australian Alps display less brilliancy of colour and are not so strongly scented, both of which facts may be correlated with the paucity of insects, but a longer vegetative period and a lower summer mean temperature must also tend to diminish the marked characters which are developed at high altitudes.

THE report of the Meteorological Service of Canada for the year ending December 31, 1901, by Mr. R. F. Stupart, the director of the department, has been received from Ottawa. The volume runs to 370 foolscap pages of meteorological statistics.

MESSRS. CROSBY LOCKWOOD AND SON have published a second edition of Mr. Tyson Sewell's "Elements of Electrical Engineering," which was reviewed in our issue for November 20, 1902. The second edition has been revised, and three chapters dealing with alternating currents have been added.

A COPY of the seventh volume of the *Transactions* of the Rochdale Literary and Scientific Society has been received. It contains an account of the proceedings of the Society for the years 1900–1903, as well as a number of the papers read before the association during these sessions. The Society is to be congratulated upon its flourishing condition, both as regards its activity and finances. The *Transactions* are published by Mr. James Clegg, of Rochdale, at 2s. 6d.

IN the review of Prof. Henrici's "Vectors and Rotors" in NATURE of October 29 (p. 617), it was mentioned that Prof. A. Lodge had suggested the use of the word "locor" to indicate a vector which has definite position, but does not indicate rotation or any rotative function. Prof. R. H. Smith writes to say that the word "locor" is used in this way throughout his book "Graphics," published by Messrs. Longmans in 1888, "rotor" being used for rotative quantities.

PARTS 9 and 10 of the first volume of the *Bulletin* of the Department of Agriculture in Jamaica are devoted to the consideration of the best means of improving the breed of horses in the island

WE have just received the report for 1902–3 of the work done in the Government Laboratory at Trinidad under the direction of Prof. Carmody. The results of a large number of seedling cane experiments, showing the relative sucrose value of different canes, form a special feature of the report.

A REMARKABLY graphic map of the British Empire, devised by Mr. Stephen Smith, is published in the October number of the *Geographical Teacher*. This map shows the British lands each in proportion to its area, and in such a position that the direction and distance from London are approximately correct. Somewhat similar results are obtained by drawing a hemisphere on an equal area projection with London in the centre, if Australasia is tacked on. Other ways of securing equivalence of area are the Mollweide and the Sanson-Flamsteed projections, where the world is shown within an oval framework. Such an oval map of the British Empire has lately been published by Messrs. Darbishire and Stanford, Ltd., Oxford.

THE question of space interference, a phenomenon first observed by V. Meyer in the case of ortho-substituted aromatic acids which can only be esterified with great difficulty, and in some cases not at all, is discussed by Prof. Skraup in connection with the cinchonine alkaloids. This interesting paper, which indicates that the alkaloids cinchonine, α-*i*-cinchonine, β-*i*-cinchonine, and allo-cinchonine have probably no fundamentally different chemical structure, but the reactions of which differ in certain respects by reason of space interference, appears in vol. xlii. of the *Sitzungsberichte* der Wiener Akademie.

IN the current number of the *Zeitschrift für physikalische Chemie*, Prof. van 't Hoff gives an account of the investigations which have been going on for some years in his laboratory relative to the transformations of gypsum. It is shown that gypsum $CaSO_4.2H_2O$ changes at 107° C. into the so-called half-hydrate $2CaSO_4.H_2O$. At this temperature, however, these two bodies are only meta-stable, for at 93° gypsum changes into the soluble form of anhydrite $CaSO_4$, which itself is in reality not stable, for under favourable conditions gypsum actually breaks up at 63°·5, and forms insoluble anhydrite found in nature and identical with dead-burnt gypsum. The laboratory investigation of these changes is rendered extremely difficult by the occurrence of retardation phenomena analogous to supercooling and supersaturation.

A RECENT number of the *Electro-Chemist and Metallurgist* contains an able article by Mr. W. C. D. Whetham on the present position of the theory of electrolysis. The investigations which led up to the theory of electrolytic dissociation and the modern convective views of electrolysis are traced, and it is clearly shown that a vast number of important observations are easily explained by the modern views. As the author points out, experiments on the comparison of the electrical and the osmotic values of ionisation are of little use from the point of view of the controversialist seeking arguments for or against the ionic dissociation theory. The deviations between the two values are, however, in most cases easily explainable by a consideration of the interionic forces, which probably exert an effect even at dilutions at which the intermolecular forces are negligible, and, further, of the complex ions which are so often formed in solution.

THE additions to the Zoological Society's Gardens during the past week include a Red-fronted Gazelle (*Gazella rufifrons*) from Senegal, presented by Lieut. F. P. Crozier; two Common Mynahs (*Acridotheres tristis*) from India, presented by Mr. H. Munt; a Hawk-billed Turtle (*Chelone imbricata*) from tropical seas, a Testaceous Snake (*Zamenis flagelliformis*) from South United States, deposited.

OUR ASTRONOMICAL COLUMN.

BRIGHT METEORS.—An exceedingly bright meteor was observed by Mr. W. Moss at South Kensington at about 11.15 p.m. on Saturday. Although not looking in the direction of its path, Mr. Moss's attention was directed to the meteor by its remarkable brightness, which he estimated as exceeding that of Jupiter. The part of the path that he observed was about 5° long, and commenced at a point near to the equator, and about 8° E. of δ Orionis. The same object was independently observed by Mr. Mills, who describes it as the brightest he has yet seen, and states that it first appeared about 5° due east of γ Orionis, and, travelling in a south-easterly direction, appeared to burst when approximately 8° or 10° to the N.E. of Rigel.

Several meteors, six of which were probably Leonids, were observed by Mr. W. E. Rolston at South Kensington during an intermittent watch which lasted from 10 p.m. on Saturday until 4.30 a.m. on Sunday. The brightest of the six was one which appeared at about 3.15 on Sunday morning in R.A. 7h. 10m. Dec. +6°, and disappeared at R.A. 6h. 30m., Dec. +5°, leaving behind it a green broken trail which lasted for about two seconds. The same observer also saw more than 50 Leonids during a watch from 2.15 to 3.45 on Monday morning. These meteors presented the characteristics of the November shower inasmuch as they were exceedingly swift and left broken trails of a reddish hue.

Mr. A. M. Davies, writing from Amersham, Bucks, states that about 10.45 p.m. on November 14 he saw a brilliant meteor with a train move westwards in an almost horizontal path at about the altitude of η Ursæ Majoris.

SEARCH-EPHEMERIS FOR FAYE'S COMET.—Herr E. Strömgren publishes a further portion of his ephemeris for Faye's comet in No. 3913 of the *Astronomische Nachrichten*. This ephemeris takes the time of perihelion passage as June 3·64, and is given below:—

Ephemeris 12h. (M.T. Berlin).

THE SECULAR VARIATION OF STARLIGHT.—In a research on the secular variation of starlight, that is, the minute yet regular variations in magnitudes which take centuries to become evident, Mr. J. E. Gore has compared the present magnitudes of a number of stars with their respective magnitudes as recorded by Al-Sufi and Ptolemy. Recognising the important bearing of these variations on the theory of stellar evolution, he selected a number of stars having spectra of the first and second types for the comparison, and has published the details of his research in the November number of the *Observatory*, giving in each case the type of spectrum, the recently estimated magnitude, and the magnitude as recorded by Al-Sufi and Ptolemy, together with remarks on the validity of the latter. Mr. Gore has prepared two lists, one of which contains the data concerning 20 stars which are apparently decreasing in magnitude; the other deals with 20 stars which show an apparent increase. He points out in his remarks that in many cases the stars which are decreasing in magnitude have spectra of Pickering's "A" type, which, according to Sir Norman Lockyer's classification, would place them amongst those which are decreasing in temperature, and therefore, presumably, in magnitude; a well-known example of this agreement occurs in the case of β Leonis, which, according to Sir Norman Lockyer, must be placed on the *descending* side of his temperature curve, and, according to Mr. Gore's result, has decreased in magnitude from 1·0 in Al-Sufi's time to 2·2 at the present day.

SOLAR OBSERVATIONS AT LYONS OBSERVATORY DURING 1902.—In his annual report for 1902, M. J. Guillaume, director of the Lyons Observatory, states that the solar surface was observed on 236 days during the year, and was reported as being free from spots on 161 days. Thirty-three groups of spots were observed, their mean latitude being 21°·0, an increase of 5°·3 over last year's value. According to the Lyons observations the last sun-spot minimum took place at the end of 1901.

The observations of faculæ show an increase in the number of groups, and the area covered by them, over the two preceding years; they also indicate that the mean latitudes of spots and faculæ do not show a parallel variation, and from this, and the differences exhibited in their persistence and activity, M. Guillaume arrives at the conclusion that it is really the faculæ which indicate the regions of principal activity, the spots being only of secondary importance in this matter. This conclusion is supported by the various tables which accompany the report in the November issue of the *Bulletin* de la Société de France.

METEOROLOGICAL OBSERVATIONS WITH KITES AT SEA.

THE following extracts from a communication to our contemporary *Science* by Mr. A. L. Rotch indicate the rapid progress which is being made in the exploration of the upper air by means of kites from ships, and a scheme for further investigation.

The first to repeat the pioneer experiments of the late Mr. Sweetland and the writer during their voyage across the North Atlantic in 1901 were Messrs. Berson and Elias, of the Prussian Meteorological Institute, who, last August, made a voyage from Germany to Spitzbergen and back, achieving satisfactory results with their kites. Meanwhile Prof. Köppen, of the Deutsche Seewarte, carried out analogous experiments on the Baltic Sea. About the same time, Mr. Dines, aided by grants from the Royal Meteorological Society and the British Association, employed a small steamer for kite-flying off the west coast of Scotland, in connection with a fixed station on land.

Meteorological kites have recently been flown from steamboats on Lake Constance by Count von Zeppelin and Prof. Hergesell on some of the term-days of the international balloon ascensions. Similar experiments upon the smaller lakes of Prussia and Russia have also shown that kites may be rendered nearly independent of the wind even in the interior of the continents.

A most remarkable campaign has been conducted by M. Teisserenc de Bort, who, with the aid of Scandinavian colleagues, established last summer a kite-flying station in Jutland, Denmark, where aërial soundings were made day and night, wind permitting, during nine months. After the termination of this work the apparatus was transferred to a Danish gunboat, and on a cruise in the Baltic Sea the following extraordinary results were obtained on five consecutive days:—April 22, at an altitude of 9450 feet a temperature of +14°.8 F. was found; April 23, at 13,500 feet, the temperature was 9°.1; April 24, at 4660 feet, 38°.3. On April 25 an altitude of 19,360 feet, which is probably the greatest height ever reached by a kite, was exceeded, and an instrument on the lower portion of the wire, at a height of 7415 feet, recorded 24°.4. In this flight the total length of the wire was 38,000 feet, and the upper 4000 feet, with the highest registering instrument, broke away, but were recovered. On the morning of April 26 an altitude of 8140 feet, with a temperature of 15°.2, was obtained, and in the afternoon 13,320 feet, with a temperature of 3°.2. Since the gunboat steamed only nine and a half knots, the kites could not be flown when there was a complete absence of wind.

These various experiments amply prove the practicability of the writer's project to investigate the atmospheric strata lying above the doldrums and trade-winds, by means of kites flown from a specially chartered steamship. This plan received the approval of the International Aëronautical Congress at Berlin last year, and an application for a grant to aid its execution is now before the trustees of the Carnegie Institution. On the vessel which the Baltimore Geographical Society sent last month to the Bahamas, Dr. Fassig, of the Weather Bureau, expected to fly kites, but, owing to the substitution of a schooner for a steamer, this could not well be done, and therefore the kites were probably flown only at Nassau. These observations might serve as a starting-point for the work of the expedition proposed by the writer, which would proceed across the equator and be capable of sounding the atmosphere to the height of four miles, notwithstanding the fact that winds either too light or too strong for the kites may be encountered when the steamer is stationary.

THE COUNTY TECHNICAL LABORATORIES, CHELMSFORD.

ESSEX is one of the counties which, since the passing of the Local Taxation (Customs and Excise) Act of 1890, has devoted the whole of the funds thus provided to the purposes of higher education. At first almost the entire grant was distributed among some forty local technical instruction committees for the purpose of lectures and classes in the areas under their supervision, but by degrees the greater part has been diverted to the erection, equipment, or support of secondary and technical schools in the more important centres.

In 1892, when Sir Henry Roscoe and Prof. Meldola were members of the Essex Technical Instruction Committee, the site of an old grammar school in the centre of Chelmsford—the county town—was purchased, and part of the old school buildings were fitted up at a cost of about 300*l.* as the county laboratories for teaching biology and chemistry, the two sciences which are of greatest importance to the principal industries of the county, viz. agriculture, horticulture, dairying and fisheries. In the temporary accommodation thus provided most of the work of the past ten years has been carried on, and readers of NATURE have from time to time had an opportunity of judging its character.

From the commencement until he was appointed agricultural biologist to the Irish Board of Agriculture in the spring of 1902, the committee had the advantage of the services of Mr. David Houston as staff-teacher of biology. Mr. Houston's influence was directed towards basing the teaching of science on practical laboratory work. It thus comes about that the institution has always been known as, and still remains, the Laboratories for Technical Instruction of the County of Essex. Moreover, the subcommittee, which now has the supervision of the laboratories, a committee which, with the single exception of the chairman, entirely consists of Essex farmers, adopted plans for the new buildings, opened by the President of the Board of Agriculture on October 30, which mainly consist of laboratories and work-rooms, and include only one lecture-room in the whole institution.

The part of the old site on which the new buildings are placed is within a stone's throw of the market-place and corn exchange, and the intention is to provide, not merely a technical school for the younger men, but also a centre at which farmers and others can readily obtain scientific and practical information respecting farming and the allied industries. Thus the principal room, near the entrance on the ground floor, is the large agricultural room, provided with demonstration and work tables for the agricultural instruction of students, and also containing an agricultural museum and reference library, together with diagram frames for displaying the most recent results of agricultural experiments. The room will be kept supplied with the agricultural papers, and will serve for the meetings of farmers which are held from time to time on market days to discuss agricultural problems.

On the same floor are the rooms for the head of the chemical and agricultural department, the work-room of the assistant who has the management of the field experiments, a small physical room with dark room for optical and photographic work, the common rooms for men and women students, and one of the biological laboratories.

On the first floor is a chemical laboratory capable of accommodating twenty students at a time; each working bench is provided with drawers and lockers for four sets of students, so that eighty students can be taught in a term. All the students' benches face the demonstration table, and thus the teaching can be carried on by revision, demonstration or experimental work without the students leaving their benches. Adjoining are the balance room and store room, the latter in direct communication with the chemical lecture room, and a private laboratory for the analysis of soils, manures, feeding-stuffs, milk, &c., for farmers, a department of the work which is found to be a most potent means for spreading information.

On the same floor are some of the rooms of the biological department, but shut off from the chemical department and reached by a separate staircase. Thus horticultural students, for whom the biological staff is responsible, are kept separate from the agricultural students, for whom the chemical staff is responsible. The common room for all the male students stands between the two departments. This system of separate staircases has the additional advantage of saving room, for a striking feature of the general plan is that there is only one corridor in the whole building. The biological department includes two large laboratories, each provided with a preparation or private work-room, a lecturer's private room, a store room, and museum galleries. The two laboratories each accommodate twenty students, and, as in the chemical laboratory, the working tables all face the demonstration table and black board.

A cool, lofty and well-lighted basement serves admirably for the dairy. The accommodation includes a milk receiving room, which it is proposed to equip with separator, pasteuriser, and steam apparatus for cleaning milk churns, &c., the dairy proper, with butter churns for twelve students, a cheese-making room, a cheese-ripening room and store. A top floor of six rooms is at present used as a part of the County Education Offices, but these are to be diverted to teaching purposes at the end of two years, when it is expected that the teaching or experimental work of the laboratories will demand increased space. The whole building is lit with electricity. The electric current is also used for motive power where required, and adapted to electrolytic purposes in the chemical and physical laboratories.

Within three-quarters of a mile of the laboratories is the school garden, which has already been planted about five years. It is three acres in extent, and is provided with a students' potting shed and glass houses, and consists partly of botanical plots and partly of fruit, vegetable and flower borders for the practical instruction of gardening students in each branch of horticulture. There is no farm in connection with the laboratories; the agricultural students make excursions to well-managed farms in the neighbour-

hood, and the field experiments are carried out on farms in all parts of the county, this system having the double advantage that manurial trials can be made on every class of land, and that farmers in each district are able to see for themselves the results.

THE NEWCOMEN ENGINE.[1]

A GREAT deal has been written on the steam-engine generally, but the author has not met with any connected record of the invention and construction of the first steam-engine—the atmospheric engine of Newcomen. Unfortunately it does not appear that very detailed information is available, but the author has been able to bring together some facts which, with the aid of appendices contributed by others and some illustrations of the engine itself, may be found to be a useful contribution to place on record in the *Proceedings* of the Institution. There are not many examples of the engine now in existence, and when they are consigned to the scrap heap, the receptacle of great efforts of the past, all will perhaps be forgotten.

Towards the end of the seventeenth century, philosophers and mathematicians searched for a new method of obtaining motive power. Mining was an important industry requiring in most cases a new power, that the mines might be worked to greater depths. Water-power, where available, was often insufficient, and manual and animal power was altogether too small and too expensive for working any but shallow mines. Deep mining was, and is, only possible with pumping machinery. Water-wheels were used for working pumps. The construction of the common pump was known. Papin had proposed to transmit power by means of pistons moving in cylinders acted on by the atmosphere, a vacuum having been formed under the pistons by the explosion of gunpowder, and he even hinted that it might be done by steam.

It was claimed for Papin that he invented the steam-engine, because in 1685, in one of his letters, he illustrated what was known of the properties of steam by saying that if water was put in the bottom of a cylinder under a piston, and the cylinder be put on a fire, the water would evaporate and raise the piston, and that if, after the piston had been raised, the cylinder were removed from the fire and cooled, the steam would condense and the piston would descend; but this was only an illustration of common knowledge. Sir Samuel Morland had, in 1683, stated[2] that steam occupied about two thousand times the space of the water from which it was produced, and made some calculations as to the powers to be obtained from different sized cylinders, but suggested no practical mode of operation. An experiment to determine the density of steam was made by John Payne in 1741. Payne concluded, as the result of his experiments, published in the *Phil. Trans.*, vol. xli. p. 821, that one cubic inch of water formed 4000 cubic inches of steam. Beighton calculated, from an experiment with the Griff engine, the second Newcomen engine erected, that the specific volume of steam was 2893.

The properties of steam were, probably, no better known to philosophers than to the ordinary observer who had seen the lid of a kettle dance under pressure, or steam issue from the spout. The only practical application of steam was made by Savery, who, in 1696, described his invention in a pamphlet entitled "The Miner's Friend." Savery's engine was a pistonless steam pump—in fact, the pulsometer of to-day without its automatic action. It remained for Newcomen to associate the bits of common knowledge in his mind for inventing the steam-engine. He was a blacksmith, probably accustomed to invent methods of construction in the prosecution of his art. At that time mechanics were more self-reliant than they are now. He knew from experience what a lever was, a pump, a piston, a cylinder, a boiler, and he knew that the atmosphere had pressure, and that steam possessed a far greater volume than the water which produced it. It did not require much more than common knowledge and observation to realise that. To produce the steam-engine from such known facts required invention. Philosophers probably knew what might be done, but Newcomen had the advantage of seeing what could be done, and he did it. The engine, when produced, was imperfect, but defects became obvious to the designers and constructor of steam-engines, and the want of perfection at the present day is not from want of theory, but because of practical limitations and want of practical invention.

At this distance of time it is difficult to appreciate the invention required to produce the atmospheric engine from the crude ideas of Papin and others. It appears, from papers in possession of the Royal Society, that Dr. Hooke had demonstrated the impracticability of Papin's scheme, and, in a letter addressed to Newcomen, advised him not to attempt to make a machine on that principle, adding, however, that if Papin could produce a speedy vacuum, his work would be done.[1] A great deal of controversy hangs about this as about all things historical, and little is to be gained by minute research into disputed claims. What we do with certainty know is that with the common knowledge existing, and the mechanical contrivances available, Newcomen alone succeeded in making a workable engine.

In 1698, Thomas Savery, of London, obtained a patent for raising water by the elasticity of steam.[2] It is stated in many popular histories that in 1705 Thomas Newcomen, John Cawley, of Dartmouth, and Thomas Savery, of London, secured a patent for "condensing the steam introduced under a piston and producing a reciprocating motion by attaching it to a lever," but no record of such a patent exists in the Patent Office. Stuart gives a list of patents commencing with 1698, and in that list is one said to have been granted in 1705. Dr. Pole, author of "The Cornish Engine," had a search made at the Patent Office and no such record could be found. It is possible that Savery's patent was thought to cover Newcomen's invention (as Savery was associated with Newcomen).[3] This was sixty-four years before Watt invented his separate condenser. Very little is known of Newcomen. It is recorded that he was a blacksmith or ironmonger residing at Dartmouth, in Devonshire, and that he was employed by Savery to do some work in connection with his water-raising engines. In this way he had some experience in the condensation of steam.[4]

Newcomen appears to have conceived the idea of using a piston for giving motion to pumps. He became associated with John Cawley, a glazier of Dartmouth, probably for business reasons. His connection with Savery was doubtless because of Savery's patent for condensing steam for raising water. He must, however, have been a good mechanic, because the construction of such an engine at a time when there was no previous experience or data to guide him was a task of no ordinary magnitude. He could not get workmen skilful enough to do his work until, erecting an engine near Dudley in 1712, he secured the assistance of mechanics from Birmingham.

The Newcomen engine was soon brought into use, for in 1712 Newcomen, through the acquaintance of Mr. Potter, of Bromsgrove, erected an engine, near Dudley Castle, for a Mr. Back, of Wolverhampton. The cylinder of this engine was surrounded with water. The piston was packed and had a water seal. It is reported that by accident a hole in the piston admitted water into the cylinder, and the condensation thereby became so rapid compared with that produced by cooling the cylinder from the outside that the engine worked much quicker. This may or may not be correct, but it is certain that, by accident or design, the first improvement in the engine was condensation by injection in the cylinder. It appears that the second engine was erected at the Griff Colliery, in Warwickshire, in 1715. It had a 22-inch cylinder. At this time the cocks and

[1] Abstract of a paper read before the Institution of Mechanical Engineers on October 16 by Mr. Henry Davey.

[2] See Tredgold's "Steam Engine."

[1] See Stuart's "History of the Steam Engine."

[2] Savery was born at Shilston, near Modbury, in Devonshire, in 1650; died in London 1715.

[3] It appears that there is every reason to believe that Newcomen had no patent, and that his invention was supposed to be covered by Savery's patent of 1698, and that the latter was kept in force for thirty-five years, the original patent having been extended for twenty-one years.

[4] Newcomen was born at Dartmouth about the middle of the seventeenth century, and died in London in 1729. It is stated in Haydn's "Dictionary of Dates" that at the time of his death he was in London trying to secure a patent. A sketch of the house in Dartmouth occupied by Newcomen when he invented the steam-engine is shown in a pamphlet published in 1869 for Mr. Thomas Lidstone of Dartmouth.

valves were all worked by hand, but automatic devices were soon introduced. The first appears to be that of actuating the injection-cock by means of a buoy in a pipe connected to the cylinder. Desaguliers thus describes the apparatus :—"They used to work with a buoy in the cylinder enclosed in a pipe, which buoy rose when the steam was strong and opened the injection and made the stroke." It is said that a boy, Humphrey Potter,[1] added a catch or "scoggan" which the beam opened, and by this means the speed of the engine was increased from 8 or 10 to 15 strokes per minute.

Barney's illustration of the Dudley Castle engine (erected in 1712) was made in 1719, and contains the plug-frame and tumbling-weight device attributed to the invention of Beighton in 1718. It is possible that the tumbling-weight had just been added for actuating the steam-valve. The injection-valve is released by the buoy said by Desaguliers to have been enclosed in a pipe attached to the cylinder, but here shown in a pipe attached to the boiler. The scoggan is also shown, and it is clear that the only thing that Humphrey Potter added, if he added anything, was a cord to cause the plug-frame to actuate the scoggan instead of the float doing it.

Newcomen had associated with him Cawley, a plumber and glazier, and it will be observed that the pipes of the engines were at first made of lead with plumber's joints. In the early days the steam cylinders only were obtained from iron-founders, and the other parts of the engine were built by local blacksmiths, carpenters, and plumbers, under the direction of an engineer.

The engine was first fixed on a boiler of haystack form, but the vibration of the engine so loosened the joints that it was found advisable to secure the cylinder to strong wooden beams above the boiler. At a later date the engine was fixed on a separate foundation by the side of the boiler, and as time went on iron pipes were substituted for lead, and the waggon-boiler was introduced to take the place of the haystack.[2]

Among the first erectors of the Newcomen engine were the Hornblowers, in Cornwall. Newcomen visited Mr. Potter, of Bromsgrove, and erected an engine near Dudley Castle in 1712. This is the historical engine in which injection in the cylinder was first used. In the vicinity lived Joseph Hornblower, an engineer who became acquainted with Newcomen's engine, and who was sent for into Cornwall about 1720 to 1725 to erect an atmospheric engine at Wheal Rose Mine, near Truro.

It may be interesting here to observe, on the authority of Cyrus Redding, a greatgrandson of Joseph Hornblower, and author of "Yesterday and To-day," &c., that the Newcomen engine was not such a simple machine as only to require the attention of boys as stated in popular histories, but that it required the united exertion of three men to start the engine.

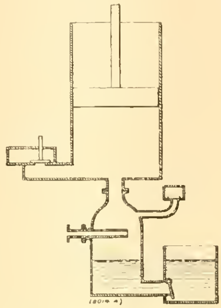
A second engine, it appears, was erected by Hornblower at Wheal Bury or Chasewater Mine. A third at Polgooth. Joseph Hornblower then left the county, and his son Jonathan came down and erected his first engine at Wheal Virgin, about 1743. The fourth son of Joseph was Jonathan Carter, the inventor of the compound engine and the double-beat steam-valves, who died at Penrhyn in 1815.

From 1720 to 1740 few engines were erected in Cornwall because of the high duty on sea-borne coal. In 1741 an Act of Parliament was passed for the remission of the duty on coal used for fire-engines for draining tin and copper mines in the county of Cornwall.[3] The effect of the passing of this Act was that by the year 1758 many engines had been brought into use; one engine at Herland had a 70-inch cylinder.

Rotative Atmospheric Engines.—It appears that attempts were made as early as 1768 to produce a rotative motion from a Newcomen engine, but it was not until about 1780 that it was successfully accomplished by the use of the crank.

It does not appear that any attempt was made, before Watt's separate condenser was invented, to reduce the cooling effect of the injection-water on the cylinder by effecting the condensation in a small vessel attached to the cylinder. It is, however, evident that after Watt's patent, Newcomen engines were made with separate condensers without air-pumps, the air being discharged through a snifting-valve. Such condensers were known as "pickle-pots."

FIG. 1.



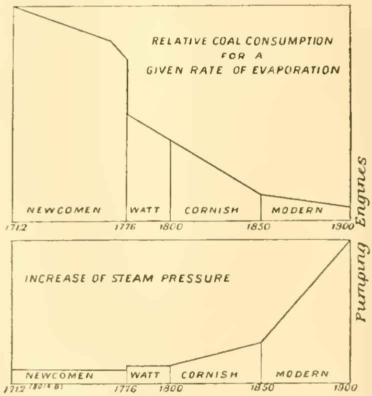


FIG. 2.

Diagrams illustrating the progress in economy of fuel and the increase of steam pressure.

In Fig. 1 will be found a sketch of the "pickle-pot" condenser. Such condensers were operated without air-pumps, as already described. It is more than probable that such condensers were not known until after Watt's invention of the separate condenser, and that they were applied to improve the economy of the Newcomen engine and to evade Watt's patent.

In Fig. 2 will also be found a diagram constructed by the author to indicate the economy of fuel resulting from various improvements commencing with the earliest engines of Newcomen. A diagram below also indicates

[1] It is curious to observe that the first engine was erected for Mr. Back through the influence of a Mr Potter. Mr. Norris writes that John and Abraham Potter were engineers in Durham, and erected an engine for Mr. Andrew Wauchope in Midlothian in or about 1725. See also Bald's "View of the Coal Trade of Scotland," pp. 18, &c., for a full account of this engine. He prints the contract in full, giving many interesting details.

[2] A drawing of almost the first Watt engine for the Birmingham Canal was illustrated in the *Engineer*, July 15, 1898. This is now erected in the yard at Ocker Hill, near Wednesbury.

[3] The Act referred to is the 14th Geo. II., Cap. xli., and intituled :—An Act for granting to His Majesty the sum of one million out of the sinking fund, and for applying other sums therein mentioned for the service of the year 1741; *and for allowing a Draw-back of the Duties upon Coals used in Fire Engines for drawing Tin and Copper mines in the County of Cornwall, &c* . . .

the rise in steam pressure corresponding to the increased economy.

The steam-engine has held its own as a prime mover for two centuries. The gas-engine has now become a more efficient heat engine, and a powerful competitor, and electricity has become an economical transmitter of power.

Heat, electricity, and mechanical work are mutually convertible. The time may come when heat may be converted into electric current with as little loss as that involved in the conversion of electric current into mechanical work; when that time comes, the heat efficiency of the prime mover will exceed that of the gas-engine in a greater degree than the gas-engine has exceeded that of the steam-engine.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The Public Orator, Dr. Sandys, of St. John's College, spoke as follows in presenting, for the complete degree of Master of Arts *honoris causa*, Mr. Howard Marsh, recently elected professor of surgery in succession to Sir George Humphry, who died in 1896.

Haud ita pridem, ut meministis omnes, plenus annis, plenus honoribus, e vita excessit vir insignis, per annos plurimos primum anatomiam, deinde chirurgiam, inter nosmet ipsos praeclare professus. Qui qualis quantusque vir fuerit, quanto scientiae amore, quanta animi alacritate, quanta sermonis facundia praeditus, non est quod longius exsequar: vosmet ipsi vobiscum recordamini. Chirurgiae vero professoris nostri primi in locum, annorum septem intervallo interposito, nuper electus est vir egregius, quem, tot aliis ministrum salutis, Academiae nomine hodie ipsum jubemus salvere. Viri talis autem inter laudes, non nostrum erit hodie scientiae tam reconditae penetralia perscrutari, non artis intimae mysteria occulta et abstrusa in lucem proferre; ne corporis quidem mala illa dura verbis duris expressa, ut ἀρθρῖτις, ut ἀγκύλωσις, totiens ab hoc viro feliciter levata, coram vobis hodie commemorabuntur. Mentis potius ad bona praeclara transibimus, et professorem nobis nuper datum propterea praesertim animo laeto accipiemus, quod ingenio tam vivido, judicio tam subacto est praeditus, in rebus minutissimis observandis tam subtilis, in rebus obscurissimis explicandis tam lucidus. Viro in ea parte medicinae quae manu curat insigni manus libenter tendimus, dextraeque tam sollerti dextram libenter jungimus. Duco ad vos baronetti quidem illustris, Jacobi Paget, quondam adjutorem, equitis autem insignis, Georgii Humphry, nunc demum successorem, virum nobis omnibus acceptissimum, Professorem Marsh.

A special course of advanced lectures on certain general aspects of zoology, to be given at the zoological laboratory during the Michaelmas and Lent terms, on Tuesdays and Saturdays at noon, commenced on November 17. The course includes lectures by the following:—Mr. Brindley, regeneration; Mr. Doncaster, (1) Weismann and his work, (2) experiments with Echinoderm eggs and larvæ; Mr. Fletcher, cell-structure, cell-division and maturation of germ-cells; Mr. J. S. Gardiner, marine fauna; Mr. Hopkins, animal pigments; Mr. Punnett, metamerism; Mr. Shipley, parasites. The first two lectures are on parasites, by Mr. Shipley. The order of the other lectures will be arranged later.

Mr. Bertram Hopkinson, son of the late Dr. John Hopkinson, F.R.S., has been elected professor of mechanism and applied mechanics in succession to Prof. Ewing. Prof. Hopkinson was placed in the first division of the first class of the mathematical tripos, part ii., in 1895, and was *proxime accessit* for the Smith's prizes in 1896.

Mr. W. Morley Fletcher, Trinity, has been appointed demonstrator of physiology.

A Clerk Maxwell studentship for research in physics will be filled up at the end of this term. Applications are to be sent to Prof. J. J. Thomson by December 18. Candidates must have worked at least one term at the Cavendish Laboratory.

The special board for medicine proposes to establish a post-graduate examination and diploma in tropical medicine and hygiene, intended to meet the needs of military, colonial, and missionary practitioners. Mr. Chamberlain and Mr. Brodrick have expressed their approval of the proposal in the interest of the imperial medical services.

A syndicate consisting of Dr. Guillemard, Dr. A. Macalister, Dr. Haddon, Prof. Ridgeway, Mr. J. G. Frazer, Mr. A. E. Shipley, Mr. W. L. H. Duckworth, and Dr. Rivers, is proposed to consider the better organisation of the study of anthropology in the University.

The Advisory Board on Military Education and Training, appointed by the Secretary of State for War in April last, has stated some of the conclusions which have been arrived at, and now carry the approval of the Secretary of State. With regard to the selection of the candidates for commissions through Sandhurst and Woolwich, it is proposed to subject them to a twofold test, consisting of a preliminary qualification and a competitive examination. The Advisory Board is of opinion that the subjects covered by the qualifying certificate (which is to be given not by a special examination, but some substitute in the shape of a "leaving certificate") must include:—(1) English; (2) history and geography; (3) mathematics (elementary); (4) French or German; (5) either (*a*) Latin or Greek, or (*b*) science. By "science" in this scheme is meant such combination of experimental or natural sciences as the Board may approve. Provided always that the sciences recognised shall have been taught in a sufficiently extended course, say three years, involving a sufficient amount of laboratory or field work. In the competitive examination the Board considers that for Woolwich candidates it should consist of three compulsory subjects, viz. English, either French or German, mathematics i., and of any two out of the following:—mathematics ii., science, history, French, German, Latin, Greek. For Sandhurst candidates they propose that there should be two compulsory subjects, viz. English, and French or German, with any two of the following:—mathematics i., mathematics ii., science, history, French, German, Greek, Latin. It consequently seems possible, and in view of public school traditions highly probable, that we may have young officers in training under the new regulations who are completely ignorant of scientific method.

Some severe criticisms of our system of education for officers in the Army were made by Lieut.-Colonel F. N. Maude at the Royal United Service Institution last week in a lecture on "Military Education." He remarked that the rising generation of young officers as a body were leaving the public schools with less education than that of many of our rank and file. In his experience, Militia, Sandhurst, and Woolwich candidates were all willing to learn, and were easily interested in their work for a time, but as a body they were mentally incapable of "concentration" for more than a few minutes. He suggested that the Government should appoint a committee of the highest specialists in nervous diseases, loss of control, and similar troubles, and get them to report on the psychological, not the physiological, influence of "drill" exercises in restoring and developing will-power in the individual. Having secured concentration, what were they to teach? Primarily, they needed the power to observe facts accurately—*i.e.* scientific teaching; next, the knowledge of facts previously registered—*i.e.* history; and, thirdly, the power to reason accurately from given data—*i.e.* mathematics. But neither history nor science could be studied without a knowledge of modern languages. History was unintelligible without physiography, geography, and topography—hence these subjects should form integral parts of its teaching. Let the Government, he said, settle a course of instruction which could only be accomplished in the time by concentration of purpose on the decisive factors, and would require in every school a thoroughly modern equipment of educational means and appliances, and, to start the system, let it send its own experts round to advise and assist headmasters. In conclusion, he strongly urged the importance of securing for the Army a good supply of older university and Militia candidates, men who joined the service not only with a fuller sense of responsibility than one found in the average schoolboy, but also with a far wider and surer basis of knowledge.

UNDER the joint auspices of the Technical Education Board of the London County Council and of the Geographical Association, two conferences will be held on Thursday, January 7, 1904, in the South-western Polytechnic, Manresa Road, Chelsea. In the morning, at 11 o'clock, Mr. H. J. Mackinder, reader in geography at Oxford, and the appointed teacher of geography in the University of London, will open a discussion on the development of geography out of nature-study. In the afternoon practical methods of teaching geography will be dealt with. Mr. Lomas, of Liverpool, will take up the question of teaching geography by excursions; Mr. T. Alford Smith, St. Dunstan's College, Catford, will describe a method of using the globe and lantern views; Mr. P. F. Kendall, of the Yorkshire College, will discuss methods of making and using models; and Mr. A. J. Herbertson, of the Oxford University School of Geography, will advocate the employment of Ordnance maps in teaching geography, and will, in particular, deal with sheets which are illustrative of typical land forms. In connection with these conferences an exhibition of geographical appliances, maps, and books of use to teachers will be arranged. It will probably be open from Tuesday, January 5, to Saturday, January 9, at the South-western Polytechnic. The Geographical Association has appointed a special committee to select exhibits.

LORD KELVIN on November 13 received the honorary degree of D.Sc. from the University of Wales. On the evening of the previous day he received the honorary membership of the South Wales Engineers' Institute, and in expressing his thanks for the honour, he remarked that engineers all over the world had still a good deal to learn as to the real value of university training. In the matter of the education of foremen in engineering works the Germans had learned how to give them scientific knowledge in a way in which we in England had not given it. It was necessary for the young engineer to learn the practical as well as the theoretical, and this could only be accomplished satisfactorily by the student's spending half his year at the university and half in the workshop, where he might learn to apply the scientific knowledge which he had acquired in the university.

AT the Sir John Cass Technical Institute, Aldgate, on Tuesday, November 17, the prizes and certificates gained by students during the past session were distributed by Sir Henry Roscoe. The institute is one of the polytechnics aided by the Technical Education Board of the London County Council and by the City Parochial Foundation. In addition to general instruction in the experimental sciences, art, commercial subjects, and domestic economy, special attention is given to the study of metals both from the scientific and the artistic side. Sir Henry Roscoe, in addressing the students, said that he hoped all present would agree with him that enough had been said about the value of the application of the principles of science and of art to industry, and that the time for work had come. Over and above the ordinary courses of instruction it is of the utmost importance that the higher work of students, especially research work, should be encouraged. What original work teaches is—how to overcome difficulties, how to obtain a mastery over opposing forces, how, in fact, successfully to tackle new problems when they present themselves, as they are ever doing to those who have eyes to see. Without this capability a man can only run in the beaten track, with it he has a weapon in his hand which gives him power to strike out new paths and to open up fresh and fertile ground. As in the scientific sphere, so also in the domain of art—the same guiding spirit holds the fort. Taste needs refinement, hand and eye require training, the craftsman, like the man of science, must be imbued with the spirit of progress as well as with a love of his art. Referring to the relation between the London University and polytechnics as regards internal students, Sir Henry Roscoe remarked that instruction given in the polytechnics must be of a real university type. It would be fatal to the prestige of the university were its necessarily high standard of efficiency lowered to meet the exigencies of the case. The course of study must be an extended one, as the hours devoted to work in the evening are necessarily shorter than those in the day; but the total time spent in study must be the same for both day and evening students, though a substantial reduction in time has been granted to those regularly employed during the day.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society.—"The Vapour Pressure of Liquid Oxygen on the Scale of the Constant-volume Oxygen Thermometer filled at different Initial Pressures." By Dr. Morris W. **Travers** and Dr. Charles J. **Fox.** Communicated by Sir William Ramsay, K.C.B., F.R.S. Received June 26.

The vapour pressures of liquid oxygen and of liquid hydrogen on the scales of the constant-volume hydrogen and helium thermometers have recently been determined by one of us in conjunction with Dr. A. Jaquerod and Mr. G. Senter, and it has been found that two scales of temperature differ by amounts which increase as the temperature falls (*Phil. Trans.*, A., vol. cc.).

	Vapour pressure	Hydrogen scale	Helium scale
Liquid oxygen	760 mm.	90°·10	90°·20
Liquid hydrogen ...	760	20·22	20·41

These results are in accordance with Callendar's calculations of the deviation from the thermodynamic scale of measurements with thermometers filled at an initial pressure of 1000 mm. of mercury at the melting point of ice. Whether the deviation becomes smaller when the thermometers are filled at a lower pressure has not been determined, and, indeed, with the means at our disposal it would be practically impossible to do so. In order, therefore, to investigate the variation of the readings of the gas thermometer with change of initial pressure, we decided to measure the vapour pressures of liquid oxygen on the scales of the constant-volume oxygen and nitrogen thermometers, for which the deviations from the thermodynamic scale are considerably greater.

Makower and Noble, using the method of Travers and Jaquerod, have found that the pressure coefficient of oxygen at an initial pressure P_o may be expressed by the formula

$$\alpha = 0{\cdot}0036642 + 0{\cdot}00000001457\ P_o,$$

where P_o is expressed in millimetres. Values derived from this expression were employed in calculating the temperatures corresponding to the vapour pressure of liquid oxygen on the scale of the oxygen thermometer filled at different initial pressures.

The results are stated in the following table:—

Gas in thermometer	Pressure on gas in thermometer at ice point	Pressure coefficient	Boiling point liquid oxyge
Helium	1000 mm.	0·00366255	90·20
Oxygen	1000	0·0036788	88·7[1]
	731	0·0036748	89·02
	658	0·0036738	89·09
	484	0·0036713	89·31
	336	0·0036692	89·48
	0	0·0036642	99·8[1]

[1] By extrapolation.

The results show that for very low pressures in the thermometer the oxygen scale converges towards the helium scale. The fact that the deviation does not appear to vanish at low pressures may be due to a tendency on the part of the gaseous molecules to associate at higher pressures

Mathematical Society, November 12.—Prof. H. Lamb, president, in the chair.—The council and officers for the ensuing session were elected. They are as follows:—president, Prof. Lamb; vice-presidents, Prof. Elliott, Dr. Hobson, Dr. Baker; treasurer, Prof. Larmor; secretaries, Prof. Love and Prof. Burnside; other members of council, Mr. Campbell, Dr. Glaisher, Mr. Grace, Mr. Macdonald, Major MacMahon, Mr. Mathews, Mr. Western, Mr. Whittaker, Mr. A. Young.—The following papers were communicated:—Prof. J. D. **Everett,** Note on Borgnet's method of dividing an angle in an arbitrary ratio. The method, which depends on the construction of a certain transcendental curve, was given by Borgnet in *Rouen. Acad.*

Travaux, 1839.—Prof. A. E. H. **Love**, The propagation of wave-motion in an isotropic elastic solid medium. The chief object of the paper is to remove a difficulty in Stokes's memoir on the dynamical theory of diffraction. Stokes's theory was built upon certain expressions for the cubical dilatation and the components of rotation, but these expressions are not always correct. A new foundation is now obtained for the theory in an independent investigation of the effects produced by force applied at one point. A knowledge of these effects renders possible the solution of a number of problems relating to wave-motion in an isotropic elastic solid, among them being the problem discussed by Stokes of the effects of arbitrary initial disturbances. It is proved that, unless certain relations connect the initial velocity and initial strain at points on the boundary of the portion of the medium which is disturbed initially, the strain in the neighbourhood of the centres of principal curvature of this surface will tend to become infinite, and fracture of the material will be produced.—Mr. H. **Hilton**, On spherical curves. The paper contains a general discussion of the curves on a sphere formed by the intersection of the sphere and any other algebraic surface.—Mr. W. H. **Young**, On sequences of sets of intervals containing a given set of points. A set of points being taken, intervals are constructed so that each interval has one of the points as an internal point, and the lengths of the intervals are diminished without limit. The author discusses the nature of the aggregate of points which throughout the limiting process remain internal points of the intervals.—The Rev. F. H. **Jackson**, A formal generalisation of Maclaurin's theorem.—Dr. H. F. **Baker**, On the Weddle quartic surface. Of the quadric surfaces which pass through six given points, those which pass through a seventh point pass also through an eighth; when these two coincide they must lie on a locus which is the surface under discussion. There is a birational relation between this surface and Kummer's sixteen-nodal quartic, and this relation is interpreted as a linear projection in space of four dimensions. From any point of Weddle's surface there can be derived by linear projections in three dimensions a remarkable figure of 32 points lying on the surface, and the formulæ by which the coordinates of these points are connected with those of the first point constitute an Abelian group.—Mr. W. H. **Jackson**, The theory of diffraction.—Mr. G. H. **Hardy**, A general theorem concerning absolutely convergent series.—Prof. R. W. **Genese**, Notes on quaternions, including a geometrical interpretation of $V\alpha\beta\gamma$.—Mr. E. T. **Whittaker**, On the expression of the electromagnetic field by means of two scalar potential functions. It is shown that the electric displacement and magnetic force due to any system of moving electrons can be expressed by second derivatives of two scalar potential functions.—Mr. P. W. **Wood**, Analogue of the Jordan lemma for four variables.

Entomological Society, October 21.—Prof. E. B. Poulton, F.R.S., president, in the chair.—Mr. J. H. **Keys** sent for exhibition a black variety of *Carabus nemoralis*, Müll., from Dartmoor.—Mr. G. C. **Champion** exhibited a series of *Rosalia alpina*, Linn., found by himself on old beech trees at Moncayo, north Spain, in July last.—Mr. A. J. **Chitty** exhibited a larva of *Dytiscus flavescens*, taken at Eastling, Kent, near the school buildings.—Colonel J. W. **Yerbury** exhibited *Gastrophilus nasalis*, Linn., taken at Torcross, Devonshire, from August 19 to 31 last. He said that as this rare species differs in a marked degree in its mode of flight, &c., from the common horse bot-fly, *Gastrophilus equi*, it would be as well to direct attention to these differences. *Gastrophilus equi*, when flying round a horse, visits as a rule the belly and the forelegs. The ♀ carries her ovipositor almost horizontal, and she looks, when on the wing, like the lower two-thirds of the letter Z (*L*), *G. nasalis*, on the other hand, carries the ovipositor tucked under the belly and almost parallel to the axis of the body; this gives her, when on the wing, a peculiar ball-like appearance; *G. nasalis*, too, always flies to the horse's head. As a rule, the horse paid no attention to *G. equi*, but *G. nasalis* caused him great alarm. The eggs of *G. equi* were in hundreds on the shoulders and forelegs of one cart-horse, but although the face and nostrils were searched carefully no signs of eggs or larvæ could be found thereon. Exhibiting *Chersodromia hirta*, Walk., he said these little Empids were common on the shore near Prawle Point; some were obtained by sweeping over seaweed, while others were running about over the sand. Colonel Yerbury also exhibited *Pamponerus germanicus*, Linn., from Barmouth and Porthcawl. He said this rare species appears to be struggling to keep its place in the British list. It appears to frequent the marram grass on the sand hills, and a ♀ taken at Barmouth on June 27 was preying on a beetle.—Mr. A. H. **Jones**, Mr. H. **Rowland-Brown**, Dr. T. A. **Chapman**, and Mr. R. W. **Lloyd** exhibited specimens of the genus Melitæa from various European localities. A discussion on the probable affinities of the several named species which occur in the Alps took place.—The president also exhibited some forms of *M. aurinia* taken by Mr. A. H. **Hamm** at Basingstoke and elsewhere, and forms of *M. athalia*, *M. didyma*, and *M. phoebe* from Asia Minor and Persia.—Dr. T. A. **Chapman** exhibited an album showing a series of photographs of the development of the embryo within the egg of *Psammotis hyalinalis* taken by Mr. W. H. Hammond and Mr. W. R. Jeffrey.—The president read, and commented upon, a paper received by him on protective coloration in its relation to mimicry, common warning colour, and sexual selection, by Mr. Abbot H. **Thayer**.

Zoological Society, November 3.—Dr. W. T. Blanford, F.R.S., vice-president, in the chair.—Dr. W. B. **Benham** communicated a memoir dealing with the aquatic Oligochæta of New Zealand.—Mr. Oldfield **Thomas** read a paper on the mammals collected at Chapadá by Mr. A. Robert during the Percy Sladen Expedition to Central Brazil, and presented to the National Museum by Mrs. Percy Sladen. No modern specimens had hitherto been obtained from this little-known region. Thirty-seven species were enumerated, four of which were described as new.—Accounts were also given of the Coleoptera by Messrs. C. J. **Gahan** and G. J. **Arrow**, and of the Lepidoptera by Mr. F. A. **Heron** and Sir George **Hampson**, Bart., collected during the Percy Sladen Expedition. The former contained an enumeration of 175 species, of which fifteen were described as new, while the latter gave a list of nineteen species, one of which was described as new.—Prof. B. C. A. **Windle** and Mr. F. G. **Parsons** communicated a paper on the muscles of ungulates; in it the muscles of the hind limb and trunk were discussed.—Dr. P. Chalmers **Mitchell** read a note on the distribution of the cypriote spiny mouse. Specimens of this form, recently described as a new species (*Acomys nesiotes*) by Miss Bate, had been presented to the Gardens, and their localities showed that this mouse extended practically all over Cyprus.—Mr. F. E. **Beddard**, F.R.S., read a paper on some points in the anatomy, chiefly of the heart and vascular system, of the Japanese salamander (*Megalobatrachus japonicus*).

Anthropological Institute, November 10.—Mr. H. Balfour, president, in the chair.—Dr. F. W. **Edridge-Green** exhibited a collection of pictures painted by colour-blind persons. Dr. Green divided the colour-blind into two distinct, independent, but associated classes. The first class consisted of persons with a spectrum shortened at one or both ends, who consequently cannot see certain rays. An individual with a shortening of the red end would not be able to see a red light at a distance, although he could pick out all the pieces in a bundle of coloured wools. The second class made mistakes through their inability to recognise the difference between certain colours. Normal sighted persons see six colours, some even seven; the second class of the colour-blind see five, four, three, two, or one colour, according to the degree of their defect, and are called pentachromic, tetrachromic, &c.—The president, on behalf of Mr. **Annandale**, read a paper on the survival of primitive implements in the Færöes and Iceland, and illustrated the paper with an exhibition of many of the implements alluded to. These included bone skates, a shovel made out of the bone of a whale, a stone lamp, and stone hammers. In the discussion which followed, the great importance of collecting these primitive implements before they entirely vanish with the advance of civilisation was insisted upon.

PARIS.

Academy of Sciences, November 9.—M. Albert Gaudry in the chair.—On the storage of the *n*-rays by certain bodies, by M. R. **Blondlot**. The rays from various sources of light, after being filtered through an aluminium screen, possess the property of increasing the luminosity of a feebly phosphorescent screen. It was noticed when a quartz lens was used that this effect continued after the source of light, an incandescent mantle, was extinguished, and it was then found that quartz, Iceland spar, fluorspar, and various other substances possessed the same property. The rays are stored throughout the whole mass, and take some time to penetrate.—On the determination of invariant figures of cyclic transformations, by M. **Rabut**.—On the approximation of functions by quadratic surds, by M. S. **Pincherle**.—Generalisation of the fundamental property of potential, by M. A. de **Saint-Germain**.—On the laws of displacement of chemical equilibrium, by M. E. **Ariès**.—The dielectric cohesion of gases at low temperatures, by M. E. **Bouty**. The dielectric cohesion of a gas at constant volume is constant to within one per cent. for temperatures between $-100°$ C. and $+200°$ C.—On a practical solution of the problem of photometry of lights of different colours, by M. Charles **Fabry**. The method involves the use of a secondary standard of the same colour as the light to be measured. For this standard, the use of a flame is recommended with two coloured solutions of definite composition.—On the scintillation of phosphorescent zinc sulphide, in presence of radium, revivified by electric discharges, by M. Th. **Tommasina**.—Remark on the latest group of solar spots and the magnetic disturbances, by M. F. **Quénisset**. Photographs of the spots taken on October 31, the date of the magnetic storm, show that the area of the sun-spots was only one-third of the area of the spots on October 11, but that on October 31 the spots were accompanied by enormous faculæ, and hence the magnetic disturbance is probably to be attributed to the latter.—On the transparency of the sea, by M. **Thoulet**. A simple relation is given between the distance, y, at which a white circle on a black background just disappears, and the amount of solid matter in suspension, x, xy being constant. The relation has been applied to the determination of the weight of the sediment in suspension in sea water.—The use of balloons containing a subsidiary air balloon according to the theory of General Meusnier, by M. Henry de la **Vaulx**. An account of two voyages in a balloon fitted with small air balloons, the latter possessing independent valves, and with a rain shield. The device of a subsidiary air balloon, suggested by General Meusnier in 1783, was found to be of great practical value. The balloon is easily kept below the clouds, and a great saving of ballast is effected, rendering longer voyages practicable.—The conditions of separation of iodine in the form of cuprous iodide, in a mixture containing alkaline chlorides, bromides, and iodides, by MM. H. **Baubigny** and P. **Rivals**. The separation is effected by an excess of copper sulphate, in the presence of an alkaline arsenite and a little ferrous sulphate.—The action of organo-magnesium compounds upon acetol and its esters, by M. André **Kling**. In no case was any haloid organic compound formed, hence, comparing with the corresponding reaction with ethylene oxide and epichlorhydrin it follows that acetol and its esters behave as ketonic compounds, and as internal ether oxides of the ethylene oxide type.—The evolution of the compound Ascidians, by M. Antoine **Pizon**.—On the regeneration in Amphibia of the posterior members and the tail, in the absence of the nervous system, by M. P. **Wintrebert**. The regeneration of the limbs is not dependent on the nervous system.—Study of the digestive ferments in some invertebrates, by M. Victor **Henri**. A comparison of the activity of the amylolytic and proteolytic ferments of *Octopus vulgaris*, *Sepia officinalis*, *Spatangus purpureus*, and *Salpa africana* with the activity of the corresponding ferments from the dog.—A new hybrid obtained by grafting, by M. Lucien **Daniel**.—On the extra floral nectars of Hevea, by MM. Aug. **Daguillon** and H. **Coupin**.—Cytological researches on *Galactinia succosa*, by M. R. **Maire**.—On the oxidation of glucose in the blood, by M. L. **Jolly**. Alcohol exists naturally in ox blood, in very minute proportion, a portion of which is further oxidised in the blood to acetic acid.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 19.

ROYAL SOCIETY, at 4.30.—The Physiological Action and Antidotes of Colubrine and Viperine Snake Venoms: Dr. L. Rogers.—On the Rapidity of the Nervous Impulse in Tall and Short Individuals: Dr. N. H. Alcock.—Electrometer Records of Secreto-motor Changes: Dr. A. D. Waller, F.R.S.—On the Nematocysts of Aeolids: G. H. Grosvenor.—The Cell Structure of the Cyanophyceæ: H. Wager.

LINNEAN SOCIETY, at 8.—A General View of the Genus Pinus: Dr. Maxwell T. Masters, F.R.S.—Contributions to the Embryology of the Amentiferæ. Part II.—*Carpinus Betulus*, Linn.: Miss Dr. M. Benson and Miss Elizabeth Sanday.

FRIDAY, NOVEMBER 20.

INSTITUTION OF MECHANICAL ENGINEERS, at 8.—Roofing Existing Shops while Work is Proceeding: R. H. Fowler.—Experiments on the Efficiency of Centrifugal Pumps: Dr. Thomas E. Stanton.

MONDAY, NOVEMBER 23.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Recent Exploration and Economical Development in Central and Western China: Lieut.-Colonel C. C. Manifold.

SOCIETY OF ARTS, at 8. The Mining of Non-Metallic Minerals: Bennett H. Brough.

TUESDAY, NOVEMBER 24.

ANTHROPOLOGICAL INSTITUTE, at 8.15.—An Engraved Tablet from Easter Island: O. M. Dalton.—The Early Pot Fabrics of Asia Minor: J. L. Myres.

INSTITUTION OF CIVIL ENGINEERS, at 8.—On the Distribution of Mean and Extreme Annual Rainfall over the British Isles: Dr. H. R. Mill.

WEDNESDAY, NOVEMBER 25.

SOCIETY OF ARTS, at 8.—The Universal Exposition at St. Louis, U.S.A., 1904: George F. Parker.

Handbook of Nature Study. For Teachers and Pupils in Elementary Schools. By D. Lange. Pp. xvi + 329; illustrated. (New York: the Macmillan Company; London: Macmillan and Co., Ltd., 1901.)

WILLIAM TURNER, whose strong religious opinions entailed for him a life of many vicissitudes in the days of Henry VIII. and his three successors, had also the makings of a good ornithologist. In his voluntary and enforced absences from England (during which he visited many European countries, and formed a friendship with Conrad Gesner), as well as in his travels in this country, he gained a knowledge of the appearance and habits of many birds which might have enabled him to write a book on the subject which would have been of surpassing interest at the present day. But, like some modern ornithologists, he was more concerned in finding out (often with doubtful success) to what species of birds certain names used by certain ancient authors really applied. So that when in 1544 he published his work on ornithology, his object was primarily to determine the principal kinds of birds named by Aristotle and Pliny.

Fortunately, however, Turner could not wholly restrain his natural bent for original observation, and here and there he added notes from his own experience, some of which form priceless items in the history of the birds of this country. In so doing (as the editor remarks) he produced the first book on birds which treats them in anything like a modern scientific spirit. He usually tells us whether he observed the various species in England or abroad, and thus Turner may fairly be called the father of British ornithology. To him we owe our knowledge of the fact that the crane bred in English fens, while his account of the abundance and audacity of the kite in his day reminds us how easy it would be to increase the remnant of these birds left to us by merely letting them alone. On the other hand, he tells us that the stork was nowhere to be seen in our island. He gives a sufficient answer to those extreme bird-protectionists who contend that the hoopoe was once abundant here and has been exterminated, for he knew the bird well, and states roundly that nowhere in the whole of Britain is the upupa to be found. His knowledge of the habits of various birds, such as the hobby, harrier, dipper, peewit, black tern and grey shrike (which he had seen not oftener than twice in England, though most frequently in Germany) is remarkable.

Turner's treatise has long been a great rarity, and ornithologists are much indebted to the editor and to the Syndics of the Cambridge University Press for making this early bird-book generally accessible.

In an appendix some extracts from a work by John Caius (1570) are added, which show that Caius was a good observer. It is interesting to note that the great rook controversy was precisely in the same condition in the sixteenth century as it is now, and that young rooks were even then appreciated.

The binding, printing, and illustrating of the "Dainty Nature Series" justify its title, although the highly-glazed paper rendered necessary for the reproduction of the numerous photographic illustrations makes the volumes very heavy to hold. Mr. Job relates his personal observations during five-and-twenty years in pursuit (chiefly with a camera) of the ducks, geese, grebes, divers, gulls, petrels, and other seafowl found in the northern and middle States and in Lower Canada, east of the Rocky Mountains. His charming work contains more new and original notes on these birds (both while at their breeding stations and in their less known winter haunts far from the shore) than any other book of this kind we have had the pleasure of reading. The illustrations are in advance of anything else of this kind we have seen. With photographs of nests and eggs we are now familiar. The present series is beautifully done, those of the ducks showing even the pattern of the "down." But it gives us a far better idea of the breeding habits of these birds when we have a view of a huge marshy sheet of water in the Magdalen Islands, where wildfowl breed in crowds; and a bit of a "slough," showing the identical clump of rushes which hides a canvas-back duck's nest, really tells us more of the bird's life-history than a picture of the actual nest and eggs. Again, the author has obtained pictures at close quarters of gulls, guillemots, &c., on or alighting at their nests. As examples of what may be found in these fascinating pages, we may point to the pictures of the great northern diver's floating nests with the surrounding scenery, grebes swimming about near their nests, a Franklin's gull eating the eggs of the eared grebe in the nest, the owner watching, shearwaters at sea fighting over cod livers thrown to them, and a petrel characteristically "walking on the water." No field ornithologist should be without this interesting book.

In "Nature Biographies" the lives of some everyday American butterflies, moths, grasshoppers, and flies are told and depicted in a delightful manner, the camera having been used most successfully in many ways; for instance, in showing the gradual develop-

ment of a butterfly emerging from the chrysalis, caterpillars feeding, the webs or tents woven and leaves curled up by caterpillars for their protection, and various insects in natural attitudes. We hardly think that "mourning-cloak butterfly" (under which name the life-history of this butterfly is ably dealt with) is any more happy than Camberwell Beauty. To read this dainty volume is to get a fair knowledge of the elements of entomology in a very pleasant way.

"The Brook Book," on lighter paper than the two volumes of this series just noticed, consists of a number of chapters describing the plants and live creatures to be met with in rambles along the banks (and in the bed) of brooks. Some of them relate the doings of a college walking party which explored their neighbourhood, and the occasional introduction of a professor or a "visiting geologist" leads to informing chapters, while the adventures of the members themselves add a vein of humour. It is impossible even to state the wide range of subjects so pleasantly dealt with, but they cover the settings and occupants of various kinds of brooks; and the enthusiasm of the writer and her pleasant way of introducing the subjects make the book just the thing to read aloud to elder children, and to instruct oneself with at the same time. The sixteen half-tone plates of brook scenery are very beautiful, and there are nearly seventy line engravings in the text.

We have in a volume of the American Sportsman's Library a capital guide to the waterfowl of North America, at once readable and scientific, and useful alike to the naturalist and the sportsman. Introductory chapters treating of the structure, character of the plumage, migrations, and the use as food and ornament of these groups, and of the necessity of affording them protection in spring, are followed by descriptions of the chief stations for wildfowling and of the various modes of shooting ducks and shore-birds. These chapters are written in the graphic language of an enthusiastic and thorough "workman." The details of actual shooting days and nights, with exciting and amusing incidents, written with a certain amount of expressive "western" words, will appeal strongly to all who have felt the glamour which hangs about "wildfowl." The body of the book is taken up with a scientific description of each species, giving details of the different stages of plumage at all ages and seasons, measurements, eggs, and habitat, followed by a general account of the habits. The waterfowl of the Pacific coast are separately dealt with, and the book closes with diagnoses of the families and genera. It is beautifully, though not profusely, illustrated, and the letterpress is printed on nice light paper, which makes this pleasing volume not too heavy to be held comfortably, despite its six hundred pages.

The object of Mr. Lange's handy volume is to point out to teachers some of the material which may be made the basis of profitable lessons in nature-study, and he has endeavoured to show how this material may be made available, and what the pupils may be taught about it. The plan here advocated is to take the children out into the fields and woods and to show them, and let them examine, various natural objects, or to bring before them prepared and preserved objects and to instruct them in these. The teacher is told how best to do this. The book, indeed, consists of a series of lessons on various natural objects, in which the requisite information is given, and the teacher is told what material is necessary and how to obtain and use it. The author has been successful in producing a valuable manual of work for children whose school years close with the common school course. The numerous woodcuts are useful and to the purpose. Unfortunately for English readers the country for which the book is especially designed is the eastern States of North America. O. V. APLIN.

THE NATURE OF ELECTRICITY AND THE CONSTITUTION OF MATTER.

Conduction of Electricity through Gases. By J. J. Thomson, D.Sc., LL.D., Ph.D., F.R.S. Pp. vi + 566. (Cambridge: University Press, 1903.) Price 16*s*.

THIS book on the newest branch of physics, from the pen of its originator and chief exponent, deals with one of the most rapid and remarkable developments of modern scientific research. The "ionisation theory of gaseous conduction," it is claimed in the preface, not only gives a simple and direct explanation of the electrical properties of gases, but also affords the means of subjecting the fundamental problems of the nature of electricity and the constitution of matter to direct experimental attack. The reason is very clearly set forth.

"The possession of a charge by the ions increases so much the ease with which they can be traced and their properties studied that as the reader will see we know far more about the ion than about the uncharged molecule."

There is food for reflection for both the man of science and the philosopher in this comprehensive remark. Less than a decade ago the possibility of the existence of a gaseous ion was hardly recognised. To-day this volume of very respectable dimensions testifies to the wealth of researches that have followed the inception of Prof. Thomson's theory. The researches of the author and his former pupils, Rutherford, Townsend, C. T. R. Wilson, Zeleny, Strutt, H. A. Wilson, Langevin and many others are brought together in this book and correlated with older researches and with those that have been proceeding simultaneously elsewhere.

In the two opening chapters the fundamental position is developed that the charge carried by the gaseous ion is the same for the ions of all gases, is independent of the ionising agency, and is equal to that carried by the hydrogen ion in electrolysis. This conclusion is arrived at from considerations of the diffusion velocity of the ions, and their velocity in an electric field, and needs only the assumption that the ions behave like the particles of a perfect gas towards pressure.

A second and completely independent determination of e for the same kind of ions is made possible by the application of the condensation experiments of C. T. R.

Wilson to the direct determination of the absolute number of ions present, and therefore of the individual charge carried by each ion. These are discussed in chapter vi., and lead to the same conclusion, that the charge is equal to that of the hydrogen ion in electrolysis. In chapter v. the ratio e/m of the charge to the mass is determined for the rapidly moving charged particles shot out by radium, by metals *in vacuo* under the influence of ultra-violet light, and by the kathode in the form of the kathode ray in the electric discharge through highly rarefied gases. A combination of the values of e found in chapters ii. and vii. with the ratio e/m found in chapter v. leads to the conclusion that m must be of the order of one-thousandth of the mass of the hydrogen atom.

On this is based the author's "corpuscular theory of electricity." The corpuscles—and it is to be noticed that the term *electron* is not used—are the discrete particles of negative electricity the presence or absence of which determines negative and positive electrification, and since the value e/m for the positive ion is never greater than for the hydrogen ion, it is concluded that a positive corpuscle does not exist, and the positive ion consists of the whole atom less one corpuscle.

The reader at this stage of the reasoning will probably question the propriety of thus combining the values found for e and e/m, for the two quantities have been determined for ions of completely different character. An earlier and more consecutive discussion of the dual character of the ion, according as to whether its charge or its energy is its chief experimental characteristic, and the adoption of some distinction in the nomenclature between the ions of the two classes, would no doubt have made the subject more clear. But it must be admitted also that this distinction, and the assumed identity of the charge for the two classes, is a point of weakness in the otherwise strictly consecutive train of reasoning. The critical stage of transition, where the ions of the first class change into the ions of the second—the slow diffusing negative ion in gases at high pressure, for example, acquiring under the action of an electric field, as the pressure of the gas is reduced, the energy and velocity of the kathode ray—seems to need further experimental study; for the conclusion that it is brought about by the ion shedding its attendant cluster of molecules and then travelling free seems mainly a consequence of regarding e as invariable. Although, no doubt, the arguments in favour of doing so are very strong, yet they appear somewhat indirect, and the anomaly that the slower moving ion is less effective as a nucleus for the condensation of moisture (p. 153) shows that the arguments are not all in its favour.

The view expressed in the chapter on ionisation by incandescent solids that the corpuscles exist in free motion inside metals and carbon, from which they escape when their kinetic energy is increased by rise of temperature, is, as the author points out, of great importance in its bearing on the variation of chemical affinity with temperature. Indeed, this book will be read by chemists with interest for the light it throws on the possible causes underlying phenomena often considered simple merely on account of their familiarity.

The chapter on Becquerel rays is the longest in the book, and comprises a brief review of the most important work in radio-activity up to the commencement of the present year. Special prominence is given to the work of Rutherford, whose application of the ionisation theory to the problems of radio-activity has been so fruitful of discoveries. The applications of the theory to the spark discharge, the electric arc and the phenomena of the vacuum tube are treated very fully, and the last chapter includes a discussion of the important results of Kaufmann on the variation of e/m with v for the rapidly moving negatively charged particle from radium. The view is expressed that these results accord with the possibility that the whole of the mass of the corpuscle is electrical in origin.

The treatment, although exhaustive, is confined strictly to the subject-matter of the title, and the recent advances in spectroscopy of the inner constitution of the atom find no place. It is interesting to notice that Prof. Thomson frankly abandons all attempt to distinguish in nomenclature between the two forms of "radiation," the undulatory and the corpuscular, with which modern physics now has to deal. Both are designated "rays," and this extension of meaning, which is practically inevitable, is, of course, in strict accordance with the original Newtonian sense of the word.

F. S.

AN ENGLISH EDITION OF "ASTRONOMY FOR EVERYBODY."

Astronomy for Everybody. A Popular Exposition of the Wonders of the Heavens. By Prof. Simon Newcomb, LL.D., with an introduction by Sir Robert S. Ball, LL.D., F.R.S. Pp. xv+341. (London: Isbister and Co., Ltd., 1903.) Price 7*s.* 6*d.*

WHEN a popular exposition of the wonders of the heavens is written by such a man as the distinguished author of this volume, the reader, and more especially he who is greatly inclined to this science, naturally expects to find not only new ideas in the art of expressing difficult issues in simple language, but judgments on various doubtful points by one who is in the foremost rank of his work. The book before us is intended, as the title indicates, for the general reader, and should therefore be not only clear, concise, and accurate, but should be illustrated with the best diagrams and pictures of the period. The reader will therefore be very disappointed to know that this standard of excellence is by no means reached in these pages.

The general scope of the book is as follows:—First, the general ideas of the motions of the celestial bodies are dealt with, the reader being also briefly introduced to the chief kinds of instruments employed in investigating the motions and physical conditions of these bodies. The sun, moon, earth, planets and their satellites are next each described, then comets and meteors come in for their turn, while a general review of the fixed stars fills up the remaining portion of the book.

The work thus covers the domain of general astronomy, with, however, one notable exception, namely, the omission of all reference to new stars! The reader is thus left entirely ignorant not only of the facts that such bodies as Nova Aurigæ, Nova Persei, Nova Geminorum, &c., ever existed, but of the various hypotheses put forward to explain the sequence of the interesting and important phenomena which are so characteristic of them.

This omission is, however, not the only blot which mars this book, for unfortunately errors of another kind are by no means uncommon.

Those who have taught astronomy know how important it is to give the student a correct idea of the difference between "rotation" and "revolution," so that the beginner may clearly grasp the facts that the former is responsible for our day and the latter for our year.

For a popular work, such as this, the definition of rotation could scarcely be more clearly explained than is done under the heading "rotation" in Webster's Dictionary (1902):—"The act of rotating or turning, as a wheel or a solid body on its axis, as distinguished from the progressive motion of a body round another body or a distant point. Thus, the daily turning of the earth on its axis is a rotation; its annual motion round the sun is a revolution."

With these definitions before us the following extracts from the book under review may be of interest. On p. 11, for instance, the reader is told that "the earth is not at rest, but *revolves* unceasingly around an axis . . .," and on the same page that "this real *revolution* of the earth, with the apparent revolution of the stars which it causes, is called the *diurnal motion*. . . ." Again, on p. 19 we read, "as the earth *revolves* on its axis. . . ."

If the author had expressly stated that his definition of "rotation" referred to *points* on the earth's *surface* and not to the earth as a whole, then the above statements might be valid, but as he makes no mention of this, the beginner will undoubtedly become perplexed as regards these motions.

A little further on (p. 35) a description is given of how the obliquity of the ecliptic produces the changes of seasons. Unfortunately (line 9) the word "orbit" is printed instead of "axis," an error which by no means renders the explanation very clear.

Another difficulty which the beginner will have to overcome occurs on p. 57, where the illustration showing the axes on which a telescope turns is placed on its side. Apropos of the incorrectness of diagrams, an error occurs in the drawing of the path of the rays (p. 68) illustrating the principle of the Newtonian reflecting telescope. Here the "flat" or "secondary mirror" is placed outside the focus of the large reflector, so that the rays which after reflection from the latter fall on it are divergent and not convergent.

In this chapter it is stated that "the largest mirrors so far successfully made and used have been about four feet in diameter." The author does not seem to be aware that the late Dr. Common constructed, mounted, and used a mirror measuring five feet in diameter.

It might also be suggested here that the diagram of the solar spectrum (p. 75) should be placed horizontally and not vertically, as this latter position would tend rather to confuse than to enlighten beginners when they are confronted later with terrestrial or celestial spectra.

On p. 114 a rather perplexing statement is made:—

"if we imagine ourselves standing *exactly* on a pole of the earth, with a flagstaff fastened in the ground, we should be carried round the flagstaff by the earth's rotation. . . ."

To the writer of this notice it seems that the flagstaff would travel round the observer if the observer be standing *exactly* on a pole of the earth as is stated; of course, it is meant that the flagstaff should be placed on a pole and the observer near it, but the reader has good cause to be puzzled.

A point which calls for special attention when giving our readers an idea of the contents of this book is the extreme poorness of the illustrations. One would have thought that advantage would be taken of the wealth and excellence of astronomical photographs that are now available, and the facility and accuracy with which they can be reproduced; but this is not the case.

Sun-spots are represented by a single drawing made many years ago; comets are illustrated by four drawings made by G. P. Bond, instead of by some of the beautiful photographs secured at recent appearances. Further, Bond's drawing of Donati's comet is so badly reproduced that probably the original artist would not be able to recognise it; the frontispiece, an impression of the solar corona of 1900, is decidedly feeble. The reader is not shown either a stellar spectrum or a reproduction of Hale's fine spectroheliograph photographs, or even a spectroscope or objective prism telescope.

From the above remarks it will be gathered that the book before us is not the best that could be placed in the hands of a beginner, and it seems a pity that more trouble was not taken in its production.

HISTORY OF ELEMENTARY MATHEMATICS.

Geschichte der Elementar-mathematik in systematischer Darstellung. By Dr. Johannes Tropfke. Erster Band. Pp. viii+332. (Leipzig: Veit and Co., 1902.) Price 8 marks.

THE great work of Moritz Cantor has made him, as it were, the Gibbon of mathematical history. But the extent of his subject has prevented him, as a rule, from entering into detail, and there are many things of great interest about which it is not easy to get information without laborious research. The history of mathematics is being studied, and its value is recognised, not only by those who make it their special domain, but by an increasing number of practical teachers, so that there is both a demand for books dealing with various parts of the subject in different degrees of detail and a school of historians ready to supply them.

Dr. Tropfke's work is not exactly a popular treatise. He has limited himself to the range of elementary

mathematics, and in this volume deals only with arithmetic and algebra; but his treatment is thorough, and his aim has been to give exact references to the original authorities for the statements in the text. The amount of labour that this has involved must have been very great; when the work is complete, with the indexes promised by the author, it will be a valuable repertory for those who wish to learn the facts at first hand. The number of bibliographical footnotes exceeds 1200, and since many of these give more than one reference, it will be seen how great a service the author has rendered to those who are inclined for research.

But the book is far from being a mere dry collection of facts and references. The style is concise, and there is no catchpenny rhetoric, but there is plenty to interest any intelligent reader. The arrangement allows us to trace in detail the development of methods and of notation; we are shown, with explanations, the actual symbols used and the processes employed by our predecessors; most important of all, there is an appendix with a selection of original examples ranging from Alchwarizmi to Leibniz and Newton. Few things are more instructive than an inspection of some of the older methods in arithmetic. Until the end of the fifteenth century, long after the decimal notation and the use of the "Arabic" numerals had become familiar, and when arithmetical calculations were usually worked on paper, the rule for performing long division was of a most complicated character, with rows of figures above the dividend as well as below, and tedious cancellings and substitutions which must have made the operation both laborious and liable to error. It is almost certain that the process is of Indian origin, and it is probable that the figures which, in written examples, we find cancelled by a stroke drawn through them represent digits which were actually obliterated at an earlier period, when the calculation was performed with a stick on a layer of sand.

A striking feature of early European books on arithmetic is the bewildering number of their so-called "rules." One reason for this is simple enough. Many of these books were intended to help business men—bankers, merchants, and so on—in such calculations as their calling obliged them to do. Their interest in arithmetic was purely practical, and all they wanted was a bundle of recipes for getting correct answers to questions of certain special types. Even in our own day we occasionally see such terms as "agricultural book-keeping" or "chemical arithmetic," which show that a demand for this sort of thing is not yet extinct. But even in treatises of a more theoretical kind *duplatio* and *mediatio*, in other words doubling and halving, were reckoned as separate rules. This is a historical survival, a sort of fossil relic of prehistoric times. It appears that the ancient Egyptians performed multiplication by a process practically equivalent to converting the multiplier into the binary scale; thus

$$x \times 13 = x \times 8 + x \times 4 + x,$$

where $x \times 8$ and $x \times 4$ were obtained by successive doubling. When an improved method of multiplication had been discovered, the older process became obsolete; but *duplatio* held its ground as a special rule, in recognition, so to speak, of its former importance.

A considerable portion of this volume is naturally devoted to the theory of surds, and this cannot be separated from the Greek theory of geometrical irrationals. After all that has been written on the subject, *lacunae* remain which will probably never be filled up, unless new documents are discovered. Some undoubted facts are very puzzling when taken in combination. For instance, Euclid says in so many words that incommensurable quantities are not related to each other as numbers, and it really does seem that to a Greek geometer of Euclid's time the relation, as to length, of the diagonal of a square to one side was something different *in kind* from the relation of two commensurable distances. At the same time the Greeks must have been practically acquainted with what we should call rational approximations to $\sqrt{2}$, and it is well known that the irrationalities considered in the tenth book of Euclid's "Elements," when put into an algebraic form, correspond exactly to all the members of a particular group of surds, without omission or redundancy. Did the geometers, who professed to despise "logistic" in public, privately make use of it to help them in their researches?

Other subjects considered under the head of algebra are the development of the idea of number in general, the operations of algebra and their symbols, proportion, and equations. Under the last heading Diophantine analysis is included, and it may be noted as a fact not generally known that Diophantine equations of the form

$$px^2 - qy^2 = r$$

were actually discussed in India at least as early as the time of Brahmagupta—that is to say, more than a thousand years before Fermat proposed the Pellian equation to the English mathematicians. G. B. M.

OUR BOOK SHELF.

La Lutte pour l'Existence et l'Évolution des Sociétés. By J. L. de Lanessan. Pp. 277. (Paris: Félix Alcan, 1903.) Price 6 francs.

The title of this book is most misleading. The reader naturally expects to find an account of the struggle for existence among primitive men and of the evolution which has resulted from the struggle. The first chapter has quotations from Buffon and Darwin which leave no doubt in one's mind that this is the line which is to be followed. After this comes a description of primitive society or rather the social system which the author assumes to be primitive. The struggle for existence drops out, and is not mentioned. Society begins, he tells us, with a severely patriarchal *régime*. He seems not to have heard of an earlier polyandrous period. Out of the family bond arose the sense of duty. Speaking of the tribe, he lays it down that the chieftain was regarded as the owner of all the land which the tribe possessed.

After this glance at primitive society, we plunge into French history. Many great questions are dealt with, and most of them with remarkable shrewdness. Our author discusses the origin of feudalism. He next decides that Christianity had nothing to do with the abolition of slavery. He traces the growth of the idea of liberty among the peasantry; it showed itself

in the *jacquerie* of the fifteenth century, which was the precursor of the revolution. He has much to say about the power of the clergy, about the national attitude of the Gallican Church followed by its eventual submission to the Pope.

With the revolution we begin to get a glimpse of what was in the author's mind when he gave his book its title. Only for a short time do the plebeians obtain liberty. Power is soon grasped once more by the well-to-do classes. What the revolution gained for the working man was the right to work when and at what work he chose. It introduced, in fact, free competition among individuals. As an individual the workman was free, but associations of workmen had as yet no legal status. Indeed, in 1791 the national assembly forbade combinations, whether among workmen or employers, intended to influence wages or prices. It is against this free competition between individuals that M. de Lanessan preaches. So far from bringing the best and strongest to the top, this Darwinian struggle for existence, as he terms it, causes nothing but misery. But has he any understanding of Darwinism? Darwin recognised not only a struggle between individuals, but a struggle between groups. If France is to hold her own against rivals, there must, no doubt, be mutual help among her citizens. There is nothing un-Darwinian in this. At the opening of the last part of the book, our author gives his views upon heredity, and it turns out that he is so Lamarckian that the struggle for existence seems to find no place in his theory of evolution; it is only a pest to be put an end to. After this, he passes on to the subject of the amount of food required by a workman, thence to alcoholism, which he attributes mainly to want of proper food, thence to the injurious effect of many of the substances employed in manufactures, thence to factory legislation. With all the main evils from which the workman suffers, the Third Republic has made an honest attempt to grapple. Before 1870 the policy of *laissez faire* was in the ascendant. There is much of interest in the book, and the style is clear, but "The Duties of the State" would have been a better title.

F. W. H.

Ore Deposits. A Discussion. Pp. 90. (New York: *Engineering and Mining Journal,* 1903.) Price 5*s.* net.

GEOLOGISTS and miners will be grateful to Mr. T. A. Rickard, the editor of the *Engineering and Mining Journal,* for having reprinted the report of a discussion upon ore deposits which took place before the Geological Society of Washington in the early part of the present year. Many leading American geologists, whose names are identified with the study of mineral deposits, were present, and took part in the discussion, so that the mining engineer now has before him, in the form of a small handy volume, a clear and authoritative statement of the views of men well qualified to express opinions upon a very difficult subject.

Geologists are accustomed to frame hypotheses upon the origin of rocks, and naturally they are dissatisfied with a classification of ore deposits dependent upon form, and favour genesis as a basis of arrangement. In this spirit Mr. W. H. Weed put forward his tentative classification of ore deposits, which occupies two and a half pages of the book. He wisely admits that ore deposits may have originated in very many ways, and says that his six classes "have been arranged to show gradation from the magmatic segregation of original igneous rocks to the deposits directly or indirectly due to the emanations from igneous rocks up to those due entirely to aqueous agencies."

Mr. J. E. Spurr followed with another classification, and Mr. C. R. Van Hise with a third. "Who shall decide when doctors disagree?" Until geologists are in harmony among themselves, the humble miner will probably do well to wait, much as he would like to have a purely genetic classification, and rest content in the meantime with his old subdivisions according to form. Besides, the miner wants something broader than a mere classification of ore deposits; he has to deal not only with ores, but also with the so-called "non-metallic" minerals, such as abrasives, borax, diamonds, gypsum, petroleum, phosphates, &c., and he consequently desires a scheme of arrangement of all mineral deposits less narrow than will be found in a treatise upon "Erzlagerstättenlehre."

Storage Battery Engineering. By Lamar Lyndon, B.E., M.E. Pp. viii+382. (New York: McGraw Publishing Co., 1903.) Price 3 dollars.

THIS book aims chiefly at treating the engineering side of storage batteries, such as the design and installation of a battery equipment, the precautions which have to be taken to maintain such an equipment in good working order, and the various accessory devices which have to be used therewith. The chemical side of the subject is treated very briefly; the first chapter, of less than a dozen pages, is all that is allotted to general theory. In the remaining chapters of the first part the characteristics of lead cells are considered in detail; the leading types of cell are described, and there is the usual series of illustrations of different grids. Considering that the book makes no pretence of being a complete treatise on accumulators, we think that much of the matter here included might with advantage have been omitted, and the material sifted with more discrimination. There are also several instances of carelessness; for example, the author speaks of forming Planté plates in a solution of litharge in *potassium,* a mistake repeated three or four times in a couple of pages. The treatment of the electrical and mechanical sides is less open to objection, and many useful suggestions are given as the results of actual experience.

The second part of the book is devoted to auxiliary apparatus; it is concerned with the use of accumulators in connection with distribution systems. The author describes at length the use of end cells or counter E.M.F. cells for voltage regulation, and the most suitable types of switches, hand regulated and automatic, to employ with them. The use of boosters and methods of wiring are considered at considerable length. On the whole the book should prove of value to the practical engineer, as it deals with an aspect of the storage battery which has not hitherto, so far as we are aware, received much systematic consideration.

M. S.

Cassell's Popular Science. Edited by Alexander S. Galt. Pp. viii+576. (London: Cassell and Co., Ltd., 1903.) Price 12*s.*

THIS handsome volume is a worthy attempt to popularise the physical, chemical, biological, and geological sciences. As the editor remarks, popular science has too often been synonymous with inexact science, and any attempt to show that scientific knowledge may be presented in an interesting manner, and be at the same time correct, is to be welcomed. The book is profusely illustrated and contains a well-selected series of brightly written essays on various subjects of pure and applied science. The volume may be recommended as a suitable present to boys and girls, who will probably by its means be led to study more deeply one of the many branches of science of which some of the methods and results are described.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Engineering Equipment of the Manchester School of Technology.

THE report on engineering work at the British Association Meeting at Southport in your issue of October 29 contains certain criticisms with regard to the engineering equipment of the Manchester School of Technology. The responsibility for the character of this equipment rests ultimately upon me as the professional adviser of the Technical Instruction Committee, and I would therefore seek some space in your valued columns for making reply.

The criticism takes two forms:—(1) that the laboratory equipment is unnecessarily complicated and beyond the capacity of the class of students the school is likely to obtain; and (2) that in any case, even if justifiable as to its nature, it was wrong to put in so much plant at once, but that part of it should have been held back until the growth of students showed a necessity for it.

The reply to both is, that it was in the hope of attracting that very class of student the critic is so sure we are unlikely to secure that so extensive and elaborate a plant was installed.

The great defect of technical education as hitherto conducted in this country has been its restriction to the teaching of elementary engineering science and to a few stock laboratory operations, such as breaking specimens in a testing machine, taking indicator diagrams from steam and gas engines, and making the simpler hydraulic experiments. This restriction was necessary, because the pupil, being a youth fresh from school, who had never seen the inside of an engineering workshop, and had to be taught everything from the commencement, could not be expected to advance very far in engineering knowledge. When he afterwards went into practical work, the knowledge acquired at the technical school being of no immediate use to him, he was no better off than if he had gone straight from school to the works, and his employer was not slow to notice this and draw the inference that the work of the technical school was practically of no value to the engineering industry. This is why the large majority of employers take so little interest in "technical education."

In Manchester, on the other hand, we have broken fresh ground, and are attempting to convince the engineering leaders that if they provide us with only one or two of the best young men out of each of their works, who have spent a few years in the workshop, and who know the elementary parts of geometry, algebra, trigonometry, and mechanics, we can, with two years of study and experimental work, turn out a product superior in every useful respect to even the much vaunted Charlottenburg *diplomé*, and of real and immediate monetary value to the profession.

We propose to prove this by showing those leaders the practical utility and industrial value of the results of our research work, and also by returning to them their young men, not mere beginners without self-confidence (though stuffed with formulæ), but trustworthy observers, resourceful experimenters, and men of imagination, who are able to impart new ideas to those engaging them, and to help them to work these ideas out in a practical way.

Take, as an example, the experimental engine to which you refer as being a huge mistake.

Take it for granted that a large percentage of the waste in steam engines is due to the defective design of valves. If we can show to some of these young designers of the future by experimental research upon this engine how these valves are defective, and in what direction to look for improvement, we are surely aiming at a higher measure of utility than could be attained by demonstrations with any number of varieties of the market article, however modern.

In regard to the remarks made about the equipment becoming obsolete, the scope and object of the plant has again been entirely misunderstood. The laboratories are not intended to serve as museums of modern appliances which the student comes to examine, copy, and store his memory with, but as a collection of machines typical of the various branches of mechanical engineering, specially fitted up for the purpose of studying the action of those working fluids and those moving mechanical elements which are common to all forms of prime movers and energy absorbers, past, present, and to come.

With reference to the question of the size of the individual parts of the equipment, one of the things for which, in my opinion, local engineers must ever feel grateful to the Manchester Technical Instruction Committee is the courage they showed in putting down plant on a true engineering scale. No practical experimental results worthy of attention could otherwise have been obtained. It could hardly be expected, for example, that an engineer, wishing to know the laws of the action of automatic drop valves for a design of large high-speed pump, should rest content to be guided by experiments made with a donkey-pump, however elaborate they might be.

In concluding, may I give expression to my belief that the promise for the future of British engineering lies in practical experimental research, strenuously carried on either in the workshop- or the college-laboratory by men specially trained for the purpose, and that the sooner we get rid of the notion that teaching schoolboys some engineering theory and the making of a few stock laboratory experiments constitutes the proper education for the engineer of to-day, the sooner we shall begin to recover from the reproach of having fallen behind the foreigner.

JOHN T. NICOLSON.

On two Constants A_1 and A_2 in the Kinetic Theory of Gases.

MAXWELL has introduced two constants A_1 and A_2 in the kinetic theory of gases (*Scientific Papers*, vol. ii. p. 41), defined by the integrals

$$A_1 = 4\sqrt{2}\ \pi\int_0^{\frac{\pi}{4}}\frac{\sin^2\theta}{\sin^2 2\phi}d\phi,$$

$$A_2 = \sqrt{2}\ \pi\int_0^{\frac{\pi}{4}}\frac{\sin^2 2\theta}{\sin^2 2\phi}d\phi,$$

where

$$\theta = \frac{\pi}{2} - \sqrt{\cos 2\phi}\ K(\sin\phi),$$

K being the complete elliptic integral of the first kind with modulus $\sin\phi$. These constants enter into the discussion of various properties of gases, on the assumption that the gas molecules repel each other according to the inverse fifth power of the distance. The values of these integrals, as found by mechanical quadrature, are

$$A_1 = 2{\cdot}6595 \qquad A_2 = 1{\cdot}3682.$$

Constructing a graph of $\sin^2\theta/\sin^2 2\phi$, I chanced to notice that the convexity is turned towards the axis of ϕ, so that the quadrature used by Maxwell must make A_1 a little too large. With the second integral, the number of points near the maximum of $\sin^2 2\theta/\sin^2 2\phi$ is insufficient, so that the value of A_2 will turn out to be too small.

Of the different methods of evaluating these two integrals, that of Gauss ("Methodus nova integralium valores per approximationem inveniendi," Werke iii. pp. 163–196) evidently leads to more accurate results than taking a number of equidistant points. This method of quadrature can be applied in two ways. The integrands $\sin^2\theta/\sin^2 2\phi$ and $\sin^2 2\theta/\sin^2 2\phi$ can be expanded either in power series of ϕ or of $q=e^{-\pi\frac{K'}{K}}$, where K and K′ are complete elliptic integrals of the first kind. Since

$$d\phi = 2/\sqrt{q}(1-4q+6q^2-8q^3+13q^4-12q^5+\ .\ .\ .)dq,$$

we can effect the approximate integration by finding either the values of ϕ or of $\sqrt{q}$ between the limits of integration, proportional to the roots of zonal harmonies of nth order $P_n(\mu)$, and proceeding according to the method indicated by Gauss.

These tedious calculations were undertaken by Messrs.

K. Aichi and T. Tanukadate, post-graduate students in physics, with the following results:—

Considered as Power Series of ϕ:

For $n=6$: $A_1=2\cdot6512$ $A_2=1\cdot3704$ (Tanukadate)
For $n=7$: $A_1=2\cdot6512$ $A_2=1\cdot3704$ (Aichi)

Considered as Power Series of $\sqrt{q}$:

For $n=4$: $A_1=2\cdot6509$ $A_2=1\cdot3750$ (A. and T.)
For $n=7$: $A_1=2\cdot6511$ $A_2=1\cdot3704$ (A. and T.)

It thus appears that the number of points for $n=4$ is insufficient, but for $n=6$ or 7 the approximation becomes very close, so that the values of these two integrals are:—

$$A_1=2\cdot6512 \qquad A_2=1\cdot3704.$$

Maxwell's value of A_1 is about 1/300 too large, and that of A_2 is about 1/600 too small. Such small differences will not materially affect the theoretical results in which these two integrals enter, but it will be worth while to notice that the actual values are slightly different from those usually given in works on the kinetic theory of gases.

Leonid Meteor Shower, 1903

THE return of the Leonids was clearly observed here on the night of November 15. The night of November 14 was also clear, though at times a dark belt of cloud, which concealed the lower part of Orion, extended itself along the eastern horizon to the foot of Leo, and occasionally also small patches of cloud dimmed or caused a momentary disappearance of stars in or around Gemini. These slight impediments to observation continued also on the next night until between two and three o'clock on the following morning. It had been intended to commence observations here as early as the night of November 11, as the writer had anticipated that the Leonids would put in an early appearance in the present year; cloudy skies, however, prevented the possibility of knowing if these anticipations were realised. During a watch from 10h. 20m. to 12h. 30m. on November 14 (local time) eleven meteors were observed, almost half of which were Leonids as bright as stars of the first or second magnitude. The radiation from Leo was regarded as surprisingly good, considering the hazy or clouded appearance of the horizon, which rendered that constellation invisible until after midnight. In a forecast made by the writer for the present year he found that, so far as the Leonid epoch of November 14–16 was concerned, the maximum would fall between the hours 13 and 14 on November 15; but it was considered that the display on the latter night would be weak, owing partly to the reported insignificance of the Leonid shower on the night of November 15, 1902, the preparations for the due observation of which were generally frustrated by unfavourable atmospheric conditions. When, therefore, the radiation from Leo was found to be so pronounced during the early hours of the night of November 14, the writer found that he had entirely underestimated the probable strength of the shower for 1903. The watch, however, was not prolonged beyond 12h. 30m. on the night of November 14, as there was no possibility of a star shower taking place on this night, though, no doubt, there were manifest signs that the Leonids might be unusually numerous. The first watch on the following night lasted from 9h. 15m. to 10h., during which time four meteors were seen, one of them being a Leonid as bright as a first magnitude star. Its appearance was revealed by the rich streak it left in its wake as it slowly rose from the invisible radiant. The watch was resumed at eleven o'clock, and whatever misgivings might have been felt for abandoning the lookout on the previous night were quickly dissipated by the appearance of as many Leonids in the first quarter of an hour's observations as had been seen during a period about five times as long on the preceding evening. Between 11h. and 11h. 30m. the meteoric rate was twenty-two per hour for one observer facing due east, but by midnight it had fallen to sixteen per hour, though sporadic meteors were included in the count. Between 12h. and 13h. drifting patches of cloud probably prevented several meteors from being observed, and the rate did not rise above thirty per hour, but at 15h., when the sky had become quite clear, Leonids were appearing at the rate of one per minute. During the next half hour forty-one shooting stars were counted, and this high rate was more than maintained for the next two hours; indeed, it was estimated at one time that the meteoric rate was easily 200 per hour for one observer. The brilliancy of the display was as remarkable as its numerical strength. When the shower was at its maximum, few of the shooting stars seen were less bright than the second or third stellar magnitude; indeed, most of them, if observed apart, would have merited individual description, and almost every third or fourth meteor might be called a bolide. To an observer looking eastwards the radiation from Leo was very marked, but a few instances were characterised by a centripetal rather than the usual centrifugal motion as regards the well-known radiant. The most noted of these exceptional cases occurred between one and two o'clock, when a bolide of surpassing splendour passed slowly downwards, leaving a rich trail across the stars ϵ and ζ Leonis. When close to the "Sickle" it exploded with a vividly white flash that imparted to it an almost startling brilliancy, and an instant afterwards a meteor as bright as Sirius made its appearance about twenty degrees further on, shooting down towards the horizon in a path that seemed to be a production of that of its more brilliant predecessor. Another meteor brighter than Jupiter shortly afterwards moved slowly downwards from within the "Sickle," passing between γ and η Leonis one-third nearer the latter than the former star, and pursuing a course parallel to the line joining η and Regulus. This west-to-east motion of the most brilliant members of a meteor display (for it has been noticed on other occasions by the writer) appears very significant. Several shooting stars shot from ϵ Leonis to β Canis Minoris, or slightly below the latter star. There seemed to be a second centre of emanation much lower down in the "Sickle" than that indicated by the foregoing meteors, and there was certainly another radiant altogether far away from Leo, and situated probably in or near Perseus. Several bolides passed out of sight overhead, arresting the attention only by their exploding flashes that momentarily illuminated the whole heavens. The pear-shaped appearance of meteors in the morning hours was very remarkable. These left rich trains which, like the meteors themselves, appeared of a yellowish tinge in the light of the waning moon or in the increasing twilight. Other members of the star shower dissolved in bright streaks, or made their appearance as vivid flashes of light, in the latter case generally at a great distance from Leo, bursting forth at one moment near the Great Bear, and in the next in the neighbourhood of Sirius. The largest number of meteors visible at one time was four. At six o'clock the activity of the shower, though considerably diminished, was still, even in the morning twilight, very noticeable.

The somewhat prolonged duration of the meteor shower affords some measure of its intensity, and it is probable that it has been widely observed, notwithstanding the fact that the notion of the supposed connection of the Leonids with the comet of 1866 precluded the possibility of such a striking meteoric occurrence in 1903, for the present is unquestionably the brightest Leonid display that has been subjected to European, and very probably also American, observation since the brilliant star showers of 1866–8. It is noteworthy that the present shower resembles very much in intensity and also in other particulars a bright display in 1865, in which year it was estimated that one thousand Leonids might have been counted by observers in England on November 13. A lapse of thirty-eight years separates the two events, and this interval suggests the nineteen year-period which has already been noticed (NATURE, April 23) in the case of all the April meteor-displays of the past century, and has also been shown (*English Mechanic*, April 3) to connect several important Leonid star-showers extending over the same time. If this be so, it is possible that the years 1904 and 1905 may be marked by even richer meteoric occurrences than that which has taken place on the present occasion.

JOHN R. HENRY.

Dublin, November 18.

Volcanic Dust, the "New Bishop's Ring," and Atmospheric Absorption.

Dr. Rotch (vol. lxviii. p. 623) may, from experience, know whether this phenomenon is more prominent in the United States than in Europe, and better than can be ascertained by simply collating reports of the sky appearances as seen by different observers in the two continents, but he is mistaken in supposing that the phenomena in question have not been mentioned in European journals, as he will find a full description of the "New Bishop's Ring" in your pages (the issue of December 25 last, p. 174), particularly as observed at Sunderland.

As stated there, there was at first a striking difference from the Krakatoa "Bishop's Ring" in dimensions, but while very variable in size, it was afterwards in general reduced to more nearly the size of the Krakatoa circle.

Since the Krakatoa phenomena this circle has rarely been wholly absent about sunrise and sunset, though for some years was faint, so far as my experience goes, until July, 1902. Whether it existed at all before the autumn of 1883 I cannot say, as one's attention was not directed to it until it became conspicuous. On its recrudescence last year it did not become visible at other times than sunrise or sunset, so far as I noticed, until August 1, and it was not until some months later that it became conspicuous in the full day-time. I can reply to the inquiry of M. Forel in your issue of August 27, p. 396, that the circle is now plainly visible, not intermittently, but always, and not only about sunrise and sunset, but in the day-time; and not only at high altitudes, but at the sea-level also. But my experience so far agrees with M. Forel's that I found in a visit to Switzerland last July and August that the higher one ascended the more conspicuous the circle became—up to a certain point at least; I did not ascend higher than 8100 feet.

In answer to Prof. Langley (p. 5) I may say that I have not noticed a single night this year or last winter when the atmosphere appeared to be normally clear, stars at a low altitude having never been clearly seen here. I had also an impression as to the want of clearness during my visit to Switzerland, but I have not yet made calculations on the observations I made for absorption. During the day-time this want of clearness has not been at all observable, the sky outside of "Bishop's Ring" having been very frequently of a beautiful blue. I note that Prof. Langley makes the abnormal absorption increase towards the violet end of the spectrum. This seems at first sight rather contrary to the circumstance that I have occasionally noticed an unusual paleness of the sun when a few degrees off the horizon; indeed, it has sometimes appeared of a slightly greenish yellow, but possibly the relative clearness shown by Prof. Langley's table at μ 0·60 may have some connection with this.

I am surprised that Prof. Langley does not attribute this condition of the atmosphere to the volcanic dust. This would seem to me much the most probable explanation.

T. W. Backhouse.

Action of Radium on Bacteria.

Continuing the experiments of one of us on the action of radium bromide on plants, we have experimented on various bacteria. We find that, in the case of *Bacillus pyocyaneus*, *B. typhosus*, *B. prodigiosus*, and *B. anthracis* in agar culture medium the β radiations from radium bromide exercise a marked inhibitory action on growth. Exposure for four days at a distance of 4·5 mm. to 5 mgr. of radium bromide does not appear sufficient to kill the bacteria, but is adequate to arrest their growth and to maintain a patch on an agar plate, inoculated with any of these organisms, sterile. A broth tube, however, inoculated from this patch has in most cases developed the organisms, showing that while the growth is inhibited in the patch all the organisms there are not killed.

MEDICAL SCIENCE AND THE ANTI-VIVISECTIONISTS.

THE vindication of law and common sense exhibited by the substantial damages awarded to Dr. Bayliss after a trial occupying the Lord Chief Justice and a special jury for four days must afford the greatest satisfaction to everyone who is aware of the long course of systematic persecution which has pursued all those who devote themselves to the scientific side of medicine, and culminated in an attack by Mr. Coleridge on Dr. Bayliss and Prof. Starling, and on University College where they work.

There are many points of interest in this particular battle between a heavily subsidised society and its victim, to some few of which we may briefly refer —but of greater interest in reality are those aspects of this case which illustrate the immemorial conflict between knowledge and ignorance.

It is amazing that in the twentieth century, when it is at length recognised, even in this country, still lagging far behind its Continental rivals, that throughout the whole field of education practical instruction is of paramount importance, we should see one scientific witness after another pressed to explain why it should be necessary for a proper comprehension of the functions of living bodies to see the parts of those bodies in motion. The most intricate machine in the world is simplicity itself compared to any living body, but who could be trusted to repair a watch, a motor car, or a marine engine who had never seen their mechanism in action? Who would trust his life to a pilot who had never been to sea, to a physician who had never studied by the bedside, or to a surgeon who had never witnessed an operation? Would anyone try to teach a child the scent of a violet out of a book? Yet in this case, so happily and justly decided against Mr. Coleridge and his Society, an eminent counsel has asked again and again why students need concern themselves with any more practical physiology (the foundation of all the knowledge they can acquire) than they can learn from the pages of a book, while to support such a plea pseudo-scientific witnesses living and dead were quoted as deliberately asserting that practical instruction is wholly superfluous.

No single error has done more to hinder the progress of medicine in the past than the common attempt to deduce function from structure without direct experimental verification. Yet in the face of the clearest lessons this fallacious method is continually urged upon us as if its utility was self-evident; of this illustrations could be cited almost without limit. The error of Erasistratus that the arteries did not contain blood, apparently supported by anatomical observation, blocked the road to knowledge for 500 years, and was only dispelled at last by Galen's simple experiment of tying an artery in two places in a living animal and opening the vessel between the ligatures. A late obstetric surgeon, whose mischievous prejudices were received with such faith and quoted with such reverence by the anti-vivisectionists, so little understood the information and arguments of the early anatomists that he imagined they had never seen blood flow from an artery, and would have been convinced of their error if they had done so. Another of his "professional convictions" was that the circulation of the blood could easily have been discovered by anyone with a syringe and a dead body, though he must have known that the syringe and the dead body had been in the hands of anatomists from the time of the Pharaohs at least, and that Malpighi, who discovered the capillary circulation by direct observation of the living frog, had previously been entirely misled by attempts to inject the blood vessels in dead animals. Harvey discovered the circulation of the blood by con-

tinual observation of the motions of the heart and blood vessels in living animals, and this epoch-making discovery is always wrongly attributed by anti-vivisectionists to the observation of the valves of the veins, though it must be clear that in that case they would have suggested to Fabricius, their observer, the real meaning of their presence and structure.

Sir Charles Bell, who has been quoted with wearisome reiteration to disparage experiments on living animals, and to exaggerate the exclusive importance of anatomical investigation, not only contradicted himself, but earned his scientific reputation by those experiments on living animals which he later condemned, and when he adhered strictly to "the just views taken from the study of anatomy" he fell into the greatest error which ever misled an eminent man. Two hundred years after Harvey had settled the question of the circulation of the blood for ever, Sir C. Bell, confusing himself with a syringe and a dead body, and unable to allow for the difference between it and a living one, came to the conclusion that the heart had little to do with the circulation of the blood, and adopted Galen's error that the principal force was the attraction of the vessels for the blood, and maintained that the law of gravity was abolished in living animals, but that Providence re-introduced it temporarily (!) for the arrest of hæmorrhage whenever an animal sustained a trifling wound.

Consistent in whole-hearted devotion to their own views, the anti-vivisectionists have misrepresented the lessons of the past and opposed every step of progress in medical knowledge in our own time. They profess to believe that every stage of progress in medicine has been effected, and always must be, by clinical work alone. Yet it is perfectly obvious that from classical times clinical investigation at Alexandria and Cordova and many other places enjoyed as great opportunities as could be desired, yet, until the opening of the renaissance of experimental method with Harvey about 1400 years later, medical knowledge had scarcely moved, for it is impossible to say that the physicians who mobbed Charles the Second to death, and who presumably represented the best talent of that time in England, and Dr. Guy Patin, Dean of the Faculty of Medicine in Paris, an eminent physician of about the same period, who maintained that all medical knowledge was summed up in senna and the lancet, had more real knowledge of physiology and the meaning of symptoms than Galen. And in modern times, when more progress in the knowledge of the causes and nature of disease has been acquired in a few years than in as many centuries formerly, every step of progress which has been obtained by physical science has been opposed by the anti-vivisectionists. Antiseptic surgery, which has brought more immediate relief from pain and death than any single discovery in the history of the human race, the whole science of bacteriology, with the light which has been thrown on tuberculosis, cholera, diphtheria, yellow fever and malaria, and the mysteries of infection and immunity, improvements in the operations of surgery, and the great names of Pasteur, Koch, and Lister, each and all have been assailed by the anti-vivisectionists with every species of abuse and disparagement.

Indeed, the denials or at best the grudging admission of the advances made in recent years in medicine and surgery would suggest that to the anti-vivisectionist they are actually unwelcome, as justifying the very researches which they attack.

It is a commonplace with Mr. Coleridge and his friends that they are actuated by the highest of all motives—love and humanity. The commonplace has been so reiterated that among the public it is taken as a matter of course, and even the Lord Chief Justice would appear to have regarded science and humanity as necessarily to be found in opposing camps. Let us see how far this claim of theirs will bear investigation.

If Mr. Coleridge and his friends were, indeed, the lovers of men and animals they declare themselves to be, no body of individuals in the kingdom would be less ready to receive or believe in stories of cruelties in others which would be incomprehensible and impossible in themselves. They would put them to the strictest tests, only accept them on the clearest proof, and rejoice unfeignedly were such proof not forthcoming.

But what really happened? A scientific man is accused of barbarities which would sicken a savage. The eye-witnesses repeatedly observe in silence tortures which a word would have ended, nay, they even withhold that word because it would have ended them, and yet Mr. Coleridge actually accepts this tale. He adopts it, he declares he has used every possible means to verify its truth, and he gives out this slander to the world, though he might easily have learned that these sufferings were inventions, and that the tortures of the defenceless creatures in whom he professed so deep an interest had never occurred at all. Is this humanity? Is this love, the love that thinketh no evil, or is it the wounded *amour propre* of one who has been worsted many times, whose statements have been refuted over and over again?

It is difficult to understand the secret of the paradoxes we are called upon to reconcile—philanthropists ascribing the basest actions to their fellow men, humanitarians diverting funds from hospitals, moralists supporting calumny by falsehood. The high motives which are claimed should exist, but until those claims rest upon some better foundation than asseverations contradicted by facts, we shall continue (and we should advise all others who are seriously considering this question to continue) to discount them altogether.

NYASALAND.[1]

MR. DUFF has written a very charming and illuminative book on Nyasaland, otherwise known as the British Central Africa Protectorate, where, since the beginning of 1898, he has resided as an official. His acquaintance with the little protectorate of 43,000 square miles was mainly limited to the Shire Province and the west coast of Lake Nyasa, but Mr. Duff is made of the same stuff as the late Prof. Henry Drummond—he is able to take in many salient points at a glance and to see things which do not strike the ordinary traveller or resident. (Whatever may be thought of Henry Drummond's later writings by scientific men, no scientific man acquainted with Africa can fail to regard his little work on Central Africa as one of the most remarkable contributions to the literature of the Dark Continent which has ever been published.)

Mr. Duff's work is illustrated by a few well chosen photographs and several of his own drawings, most of which are excellent, but one or two, perhaps, too sketchy and vague to consort with the general accuracy of the book. There are useful appendices, a sketch-map of the protectorate, and a good index.

The portions of the book which will most appeal to the readers of NATURE are those dealing with the flora, fauna, and human inhabitants, and these subjects occupy more than half of the book.

"If it be spring," writes the author, "the display of flowers will attract the attention of the most indifferent, blooms of every shape and hue being then abundant, from the great clusters of petals adorning certain papilionaceous trees down to the less conspicuous but equally beautiful ground flowers and

[1] "Nyasaland under the Foreign Office." By H. L. Duff (B.C.A.Admn.) Pp. xv + 422. (London: George Bell and Sons, 1903.) Price 12s. net.

creepers. Except, indeed, in the matter of tree-orchids, which are not very well represented, the flowers of Nyasaland are scarcely surpassed either in respect of variety or brilliancy by those of any other part of the world. It is true that, except here and there in the hills, they do not often grow so close together as to present unbroken masses of colour; and therefore the estimate which any particular person may form of them, as a whole, depends to some extent on his powers of observation. Still, short of always travelling in a machilla and always falling asleep in it, there is no possibility of overlooking them entirely. Ground-orchids flourish almost everywhere. Among lilies we have the Crinum, with its long, heavy, pure white blossoms; and a most effective little tiger-lily of bright gold and deep cardinal red; also a tree-lily (Vellozia), so wonderfully beautiful that, as Sir Harry Johnston says, 'even the botanists of Kew were touched, and called it *splendens*.' Then mauve irises spring up in countless thousands during the rains, and pink and crimson gladioli, and pale yellow marguerites, hibiscuses too, anemones, gentians, flowering beans—hundreds of plants, too, whose names are unknown to me, and many others perhaps which have escaped classification at the hands of the very few scientific botanists who have exploited the flora of the country."

The author is incorrect in some of his guesses as to the names of plants and trees. On pp. 111 and 112 the "euphorbiaceous" plant or tree to which he refers is none other than a common form of Dracæna or tree-lily, used throughout many parts of tropical Africa for hedges or enclosures.

The author has many interesting notes and original observations on the fauna. He shows that, contrary to the belief of such authorities as Sir Alfred Sharpe and Sir Harry Johnston, the roan antelope does apparently still exist in parts of the Shire Province. It has been generally supposed that this antelope confined its range within this protectorate to the regions west and north-east of Lake Nyasa, and did not intermingle, so to speak, with the area of its near ally, the sable antelope. Mr. Duff, however, shows that the roan antelope has been shot in the Shire Highlands. He alludes several times to rumours of the striped hyæna existing within the limits of the protectorate. We are, as a matter of fact, very ignorant yet as to the exact number of species or varieties of the hyæna genus existing in Africa, and the limits of the range of each species or variety. The actual range of the true striped hyæna is, of course, northern as compared to the existing southern range of the spotted hyæna. The striped hyæna is the only species of this group which at the present day is found beyond the geographical limits of Africa, its range extending through Syria, parts of Asia Minor and Arabia (? southern Persia) into Baluchistan and India. How far it penetrates into equatorial Africa is not accurately determined at the present time by indisputable evidence. It certainly reaches the Gambia River in West Africa. It is found in Abyssinia and some of the Nile countries, and in Somaliland. It has been *reported* to exist on the slopes of Kilimanjaro, and as far south as Unyamwezi, and also to be found in the eastern part of the Uganda Protectorate; but inasmuch as that curious creature the aard wolf (Proteles) very closely (in the eyes of the natives) resembles a dwarfed form of striped hyæna, and as the aard wolf is found at intervals throughout the whole eastern half of Africa from Cape Colony to Abyssinia, it is possible that some of the stories of striped hyænas existing in British Central Africa, German and British East Africa may refer only to the aard wolf. The brown

FIG. 1.—Wankonde of North Nyasa. From 'Nyasaland," by H. L. Duff.

hyæna, a distinct form, but one nearly related to the striped, also ranges, as a very scarce animal, from Natal in the south to equatorial East Africa in the north, and may possibly be found here and there within the limits of the British Central Africa Protectorate. The black and white monkey to which the author refers is obviously the Colobus, and not the Mangabey, which ape is nowhere found within the limits of British Central Africa, but is a form confined to the West African fauna, though it reaches as far as the western limits of the Uganda Protectorate.

The author gives a charming and accurate description of one of the Galago lemurs which are so common in this part of Africa. The writer of this review is convinced that the intelligence—the almost Simian intelligence—of most of the lemurs has been greatly underrated, as also their human characteristics, such as their ability (specially marked in the Galagos) of running on the hind feet and using the hands to box with. A Galago surprised and at bay puts his large fists almost into the positions of a human boxer. Of this interesting animal the author writes:—

"This lemur is a charming little thing to look at, with its soft bluish-grey fur, and large, solemn, perfectly circular eyes. It also makes a most engaging pet. I knew one which used to live half wild in the roof of a verandah at Zomba, coming and going without let or hindrance. In disposition he was on the whole very sociable, but inclined at the same time to be somewhat overburdened with a sense of his own dignity. At any rate, it was very easy to offend him; and when this happened he would retire to his coign of vantage in the roof, which nothing would then induce him to quit. At other times he would come out readily when called by his native name of "Changa." Five-o'clock tea was his favourite meal, and he rarely missed it, being accustomed about that time to refresh himself with a saucer of milk, which he drank with elaborate daintiness. His curiosity was infinite, and sometimes overcame his natural good breeding; but lapses of this kind often brought their punishment, as once, when he thrust his head unbidden into a small coffee cup and could not withdraw it. The sight of him thus unexpectedly bonneted I remember to this day. Though a certain sedateness marked his normal bearing, he possessed a truly wonderful reserve fund of activity, and could climb anything and jump anywhere when the humour took him. Moreover, he had a knack of alighting after the most prodigious leap almost as gently as a bird. I have known him to drop suddenly from a high curtain pole on to the edge of a tea tray without upsetting a single cup; but then of course he was a very small animal—smaller in fact than he looked, owing to his thick, fluffy coat."

There are interesting notes on pp. 85, 86, on the fish of Lake Nyasa, in which justice is done to the wonderful colours of the "blue perch."

On p. 124 an excellent description is given of the weird noises in the African bush at night time. The author also is wise enough to illustrate the monotony and stillness of the African landscape in day time and under normal conditions. He discourses on the singular beauties of the flora and the marvellous interest in the fauna, but brings home to his readers that every aspect in all seasons and under all conditions of Central Africa is not wonderful or beautiful or terrifying. Rather, perhaps, have many of these beauties and wonders to be sought for; they are not immediately patent to the eye of the untrained observer.

He still considers that as a game country Nyasaland may almost vie with any other part of tropical Africa where game is varied and abundant, and attributes the fact that no species in the splendid fauna is yet on the verge of extinction to the Game Laws, which have been in existence now for something like eight years, and which the Foreign Office has steadily enforced.

His chapters on the native races are admirable. He has evidently made himself well acquainted with the Chinyanja tongue, and through the medium of this widespread language has been able to get into touch with the natives of the Protectorate, thus collecting much new and valuable information regarding the manners, customs, traditions, beliefs, &c. To their amiable qualities he is fully alive, as also to their weaknesses and simple vices.

The remarks of the author regarding the labour question are well worthy of attention, but are not suited for discussion in the pages of this Journal. The same remark applies to his excellent chapter on the work of the missionaries, which is critical but appreciative.

THE CANADIAN ROCKY MOUNTAINS.[1]

THIS attractive volume is more than a record of mountain climbing. It gives the reader a very good idea of a considerable area of the Great Lone Land, its fine scenery and physical characteristics, introducing him to not a few "untrodden peaks and unfrequented valleys." Between the eastern base of the Canadian Rocky Mountains and the Pacific shore the earth's crust has been crumpled into a zone of parallel folds more than 500 miles in breadth, which have been deeply sculptured by meteoric agencies. South of the American border these mountains are distinguishable into the Rockies proper and the Sierra Nevada, parted one from another by the broad plateau of Utah, the latter chain being flanked on the west by the Coast Range. In Canada the three are practically fused together, the peaks running in successive ranges, almost like waves of the sea. Messrs. Stutfield and Collie selected as their field of work the region on both sides and immediately west of the continental watershed to the north of Hector Pass—that traversed by the Canadian Pacific Railway. This region, so far as they saw, consists entirely of sedimentary rocks—limestone, sometimes dolomitic, with shales or slates. It is, as mountaineers will see from the illustration which we reproduce, not unlike the Western Oberland, between the Blumlis Alp and the Diablerets, greatly enlarged laterally but not vertically, the higher peaks ranging commonly from about 10,500 to rather under 12,000 feet. The mountains, in fact, were less lofty than the authors had anticipated. One of their few predecessors had, indeed, reported the existence, some dozen leagues north of the railway, of two Alpine giants, Mount Brown and Mount Hooker, rising on either side of a pass, the one to an elevation of 16,000 feet, the other only 300 feet lower, and asserted that he had scaled the former. As, however, this indicated an ascent of about 9000 feet in little more than half an early summer's day, experts were sceptical; the more so when Prof. Coleman, of Toronto, ten years ago found a mountain only just more than 9000 feet high where Mount Brown should be. These giants, in the course of the explorers' four journeys, were proved to be as great impostors as the Mont Iseran and Aiguille de la Vanoise of the Graian Alps some half-century ago.

Travel in the Canadian Rockies is anything but easy work. Wood and water are the only necessaries which the country can be trusted to supply. Indians are few, and game is generally scarce, so that a loss

[1] "Climbs and Explorations in the Canadian Rockies." By Hugh E. M. Stutfield and J. Norman Collie, F.R.S. Pp. xii+343; with maps and illustrations. (London: Longmans, Green and Co., 1903.) Price 12s. 6d. net

of supplies might occasionally mean something very like starvation. Where there are any roads, these are but trails, often more than half overgrown, so that progress is apt to be slow and laborious, difficult swamps and swollen rivers have to be crossed, while mordant insects, mosquitoes and flies, are at times almost intolerable. So notwithstanding the charms of the scenery—bold peaks, fine glaciers, forest-clad slopes, and almost numberless lakelets of rare beauty—travel in the Canadian Rockies is not to be recommended to the habitués of Interlaken or Luchon. Until the Switzerland of Canada is developed—as before long it certainly will be—it can only be explored by hardy and vigorous travellers.

Game, as we have said, is scarce, but the bighorn (*Ovis Canadensis*) and the Rocky Mountain goat (*Haploceros montanus*) occur perhaps about as often as chamois in the Swiss Alps, and bears—black, brown and grizzly—are occasionally seen. Geese, ducks, and three kinds of grouse sometimes vary the *menu*, but evidently the district will hardly be tempting to sportsmen who desire "big bags." Neither do the rocks appear attractive to the palæontologist. The specimens brought back by Dr. Collie were rarely fossiliferous, even when examined under the microscope. Mr. Whymper had, on the whole, a similar experience in his explorations near and to the south of the railway, so that either subsequent mineral changes have obliterated the traces of organisms or the region in past ages was not rich in life. Dr. Collie gives an illustration of objects resembling tree trunks high up on Mount Murchison—possibly the stems of some giant alga—and picked up limestone pebbles with corals, probably Devonian or Carboniferous, in the bed of the Bush River. A few specimens contained traces of organisms, some perhaps foraminifera (misprinted foraminifer*ae*), with an ostracod (misprinted ostr*e*od); one slab showed badly preserved trilobites, probably Lower Cambrian, described by Dr. H. Woodward, and the journey of 1901 was rewarded with some remarkable tracks and other markings from Desolation Valley, south of the railway, not far from Laggan (see the *Geological Magazine* for July last).

Fig. 1.—Mount Forbes from the East. From "Climbs and Exploration in the Canadian Rockies," by H. E. M. Stutfield and Prof. J. Norman Collie.

The book is well illustrated by numerous reproduced photographs, which enable us to realise the beautiful scenery of this unfrequented land, and its topography is made clear by a map constructed from the authors' surveys. That is such as we might have expected—long troughs parallel with the general trend of the strata being connected by shorter transverse glens, as can be seen, on a smaller scale, in some parts of the Alps. In consequence of this, the Canadian Pacific Railway, as is well known, descends, west of the watershed, into a valley belonging to the Columbia system, then, after crossing a spur, strikes the same river flowing in an opposite direction, and after another mount descends to follow the Fraser River to the coast. Well illustrated and written in an attractive style, the book records a series of journeys, not always without risk, and throws much light on the geography of a region many parts of which have hitherto been very imperfectly known.

T. G. Bonney.

SCIENCE AND THE ARMY.

Many of our readers may have seen a brief preliminary official notice of the proposals of the War Office for the reform of military education. These proposals are so astonishing, in view of the facts of the case, that we take an early opportunity of directing attention to them.

There is to be, first, a qualifying test. It is intended that this shall take the form of a "leaving certificate," but in view of the probable difficulty of organising a suitable leaving examination for a long while, there seems reason to fear that, at first, this qualifying part may take the form of a special examination, which all must pass, but which will not otherwise affect the final result. This qualifying part is to consist of:—(1) English, (2) history and geography, (3) mathematics, (4) French or German, (5) either (*a*) Latin or Greek, or (*b*) science.

Then there is to be a competitive examination, in which (1) English, (2) French or German, and (3) mathematics i. will be compulsory for Woolwich candidates; and English and either French or German for Sandhurst candidates. In this examination Woolwich candidates may also offer any two of mathematics ii., science, history, French, German, Latin, Greek; and Sandhurst candidates may also offer any two of mathematics i. or mathematics ii., science, history, French, German, Greek, Latin.

The more closely we look into the probable effect of these proposals the more clearly does it appear that, under this new scheme, experimental science seems certain, by the light of past experience, to become a negligible quantity in the training of most officers. Those who read the report of the Army Education Committee published in March, 1902, may remember that the head master of Eton during the examination of a witness expressed confidently the opinion that, if Latin and science should be brought into competition in these examinations, "the science will kill the Latin." Even Dr. Warre, however, does not expect this to happen just yet, for he added, "eventually." Unfortunately for this position, we do not merely want to get a good system of army education eventually, but to get one as soon as possible,

and the figures which we quote below show how unlikely we are to get such a system under the scheme now put forward, if it be admitted, to adopt a statement taken from the report of the same committee, that experimental science, *i.e.* chemistry and physics treated experimentally, is an essential part of a sound general education. In the outlined scheme now before us—as stated above—science comes into the education of the candidates in the qualifying part as an alternative for Latin or Greek, that is to say, practically speaking, for Latin: and again in the competitive part as an alternative for Latin, French, history, &c. Now boys at school begin Latin at say eight or nine years of age. They probably rarely begin the experimental science proposed before thirteen or fourteen. If the candidates are to do a three years' course in chemistry and physics, as suggested, they must begin it at fourteen or sooner, in order to be ready for the qualifying part at, say, seventeen, which seems likely to be about the age at which we may expect most candidates will take this part. This means that at about fourteen the choice must be made between science and Latin.

But at fourteen a candidate will have studied Latin, French, &c., for years. He, his masters and his parents will know a good deal about his prospects in these subjects. Whilst, from what we have said, it is obvious that in most cases they will know nothing about his prospects in science at that age. Can it be doubted that nearly all the cleverer boys, and most even of those whose abilities are second rate, will neglect science at every stage—that, as a rule, only those who are really bad at Latin will get any science? Again, is it reasonable to suppose that candidates whose early education has included no experimental science will at the eleventh hour give up one of the subjects in which they are somewhat advanced, and take to a subject in which they are untried and untrained? Must it not happen that the average officer of the future will know nothing of, and care nothing for, science or its methods, be incapable of appreciating its importance to his profession, and incapable, even, of using the knowledge of others from ignorance of their language and methods of thought? This scheme must result most disastrously in its effect on the army and on the schools.

It has been suggested that the parents will select and insist on the science. We do not believe it. There is a strongly flowing current in favour of science among the parents. That is true. But how can any reasonable parent be expected to insist on his son taking up the subject which seems least likely to conduce to success in a competition of vital importance to him?

But this question is not really a matter of opinion at all.

Some years ago science, in both Woolwich and Sandhurst competitions, had to compete in a somewhat similar way with several other subjects which are begun earlier than the experimental science at schools, and on conditions which were, we think, not so very much more unfavourable than those now proposed. From computations that have been made for us, we find that at that time one successful Sandhurst candidate in twelve ventured to offer experimental science For Woolwich, even, though there were well-known advantages in starting at the Royal Military Academy with a scientific training, which no doubt will still exist, the proportion who offered science was only 22 per cent., or say one in five, of the whole.

As the majority of the candidates will continue for some time to come to be derived from the same classes as in the past, why should we expect a more favourable result now? Some years ago Sir Henry Roscoe and others came forward as the champions of science, and, aided by the head masters of Rugby, Cheltenham, Clifton, and other schools, and by insistently directing attention to these and similar facts, presently secured a more reasonable system in many respects. No doubt the science arrangements made then need revision now in many of their details. But the need for science training among our officers, the need for a fuller appreciation among them of the part it plays, the absolute need to start a training in science, as in languages and mathematics, at an early stage of a boy's training; and, above all, the importance of not teaching young officers to regard it as unimportant by neglecting it at the schools or afterwards, were never greater than at this moment. Who among our leaders in science will come forward in this fresh emergency?

PROF. ALEXANDER ROLLETT.

PROF. ALEXANDER ROLLETT, of the University of Graz, the eminent physiologist, died on October 1 at the age of sixty-nine. His name, though not associated with any particularly brilliant discovery, is well known to science as that of a diligent and successful worker.

Descended from a family of doctors, both his father and grandfather having been more or less distinguished physicians in Baden, near Vienna, Alexander Rollett commenced his medical studies in the dawn of the great era of physiological science under the guidance of Carl Ludwig and of Ernst Brücke, then newly appointed professor of physiology in Vienna.

In 1858, having completed his course of studies, Rollett became Brücke's assistant, and in 1863 was appointed to the professorship in Graz, which he retained until his death. Like his great masters, Rollett's investigations extended to widely different subjects, but by preference to problems that involve the use of histological methods. His principal researches may be summed up under no less than four distinct headings:—chemistry and histology of connective tissue, chemistry and histology of blood, histology and physiology of muscle, and work on sight and other senses. Three of these different subjects Rollett subsequently treated at length in several standard publications.

We find Rollett first studying the composition and structure of the connective tissues, and demonstrating that mucine is a prime constituent of these substances. His work on this subject, and especially on the cornea, he later on embodied in the corresponding chapters of Stricker's "Handbuch der Gewebelehre." He then turned his attention to the chemical and histological properties of the blood, and it was he that first performed the well-known experiment of "laking" blood by alternate freezing and thawing, and by repeated discharges of electricity. The theory of the "stroma" of the red corpuscles is likewise founded largely on Rollett's observations. By these and other discoveries he attained the rank of a prime authority on the physiology of blood, so that when Hermann edited his well-known "Handbuch," the chapter on blood fell to Rollett's share.

On the intricate subject of the structure of striated muscle Rollett brought to bear his powers of histological analysis, and added new comparative data of value by his observations on the muscles of bats, of insects, and of other invertebrates. At a much later period Rollett again approached the study of muscle from a physiological point of view, and published important observations on the velocity of the contraction wave and on exhaustion phenomena. On the

histology and physiology of muscle generally Rollett wrote in Eulenburg's "Encyclopædie." To physiological optics he contributed several papers on spatial perception, on contrast, on the effect of plane parallel glass plates, and various other subjects. He was also one of the first discoverers of sense organs in tendons, and published various observations on the sense of taste, of smell, and on cutaneous sensations.

That Rollett was no less of a teacher than of an observer is proved by the success of many of his pupils. The University of Graz acknowledged his merit by choosing him for rector no less than four different years, including the year of inauguration of the new buildings, when the Emperor and other illustrious guests were to be received. Rollett was also frequently elected as a representative on the local board, and the organisation of the new physiological institute, built under his supervision, testifies to his practical ability.

Most scientific men are naturally diffident to commit themselves in writing to a verdict on the merit of a fellow worker, but it is a curious fact that in verbal conversation this diffidence does not appear. The mere way in which the name of an observer is mentioned is often equivalent to a fairly strong expression of opinion. A careful and conscientious observer commands a degree of admiration and reverence that affects the tone of every chance remark. Judged by this standard, Alexander Rollett was a true follower of science. R. DU BOIS-REYMOND.

NOTES.

A RUMOUR has reached us that at the annual meeting of the Royal Society on Monday next an attempt is to be made by a certain section of the fellows to upset the selection of officers made last week by the council. It appears that the physiologists are under the belief that they have acquired a prescriptive right to hold one of the two secretaryships. It is true that for upwards of forty years they have so held it, but the group of natural sciences includes more than physiology or even biology, and the council, in the exercise of its discretion, has thought that it was high time that one of the other sciences should be represented in this secretaryship. We are further informed that a copy of a letter is being circulated which appears to convey an invitation from the president and council to a certain physiologist to accept the vacant office. That letter was, it is stated, written in error, without the sanction or knowledge of the president and council, but in view of it a special meeting was called to consider the matter, when the council decided to adhere to the decision at which they had already arrived in the ordinary and regular way—a decision which is obviously in the best interests of the Royal Society as a whole, and doubtless the great majority of the fellows will support it by their votes on Monday.

A CORRESPONDENT of the *Times* directs attention to the wise recognition given to science and other branches of learning by Continental nations on all occasions of national importance; and the comparison he makes with our own official customs is not creditable to our dignity. When a monarch or the supreme authority of a State visits the Court of another nation, men of "light and leading" are usually invited as guests to meet him. These are the men who give distinction to a nation; and a people which fosters intellectual accomplishments cannot conceive a State function in which they are not represented. Here, however, there is little pride in the glory which learning brings to a State, and little encouragement is given to the men who devote themselves to the advance of knowledge. Not a single writer, painter, sculptor, architect, musician or man of science of distinguished eminence was invited to Windsor or to the Guildhall to meet the King and Queen of Italy during the recent visit; and the omission, inconceivable to a foreigner, is characteristic of our customs. The *Times* correspondent concludes his letter with the following remark, with which we are entirely in sympathy:—"I believe I shall be expressing the opinion of many of my countrymen if I say that it is much to be regretted that, on great national occasions, persons of titular rank, of great wealth, or of political prominence should be considered adequately representative of the Realm, and that the arts and sciences should be ignored, as though they were non-existent among us."

SINCE the termination of the Bayliss *versus* Coleridge case, which is discussed in another part of this issue, two further communications, which appear to us as striking confirmation of the views expressed in our article, have been received by the daily papers; they are:—(1) a letter from Mr. Coleridge in which he announces that he has paid the damages (which would be interesting, had it been optional) and that he intends to continue on his former courses; (2) a letter from Mr. Bayliss, from which we learn that the large sum which he might, after having personally borne the expense and long months of worry, have used, with perfect justice, for his own advantage, has been devoted by him to the furtherance of that branch of physical science which was the object of the recent attack. Mr. Bayliss's employment of this money as a public trust is in complete consonance with the sense of public duty which has actuated his conduct throughout this matter. It will be endorsed by English physiologists and by the public as forming a worthy and fitting termination to the struggle which has been followed with so widespread an interest.

A REUTER message from Buenos Ayres announces that the Argentine war vessel *Uruguay* has arrived at Rio Gallegos with the members of the Nordenskjöld Antarctic Expedition on board. Two of the missing Swedish explorers were found on Seymour Island on November 8, and others at Snow Hill. The *Uruguay* then proceeded to Paulete Island, where the main body had wintered, and took the remaining members of the expedition on board. Dr. Nordenskjöld's expedition left Falmouth in the steam yacht *Antarctic* in October, 1901, and he expected to be home again early in the present year. From the outset of the voyage the expedition met with countless difficulties owing to the state of the ice. In December, 1902, the vessel reached the north-east coast of Louis Philippe Land, where Dr. Nordenskjöld, Lieutenant Anderson, and two sailors were left at Mount Bransfield. Dr. Nordenskjöld proposed to proceed to Snow Hill in sledges. It was arranged that Mount Bransfield should be the rendezvous for the whole expedition. The *Antarctic* meanwhile made her way to the east of Joinville Island and entered Erebus and Terror Bay. There she was caught in the ice, which finally crushed and sank her. Captain Larsen succeeded in saving all on board, and the party took to three of the ship's boats, which they equipped with provisions. They drifted about for sixteen days, and finally reached Paulete Island, where they established their winter quarters. In September, 1902, Dr. Nordenskjöld, accompanied by Lieutenant Sobral and one sailor, made a sledge journey with two sledges and five dogs in a south-westerly direction. Travelling by way of King Oscar Land, a latitude of 66 degrees was reached, the longitude being 62 degrees west. The party returned to Snow Hill at the beginning

of November, after having made a journey of more than 400 miles, in the course of which new bays and islands were found, and other discoveries were made involving important changes in the existing maps of the region. While awaiting the return of the *Antarctic*, Dr. Nordenskjöld was engaged in geological, magnetic, and meteorological observations, and got together important collections of fossils, plants, and animals. During the first winter the mean temperature was $-12°$ F. below zero, but in August it went down to $-42°$ F.

M. BORDAS, formerly assistant director of the Municipal Laboratory of Paris, has been appointed head of the laboratories of the French Minister of Finance, to succeed M. de Luynes, who is to be styled honorary director.

THE Engineering Standards Committee has appointed Messrs. Crosby Lockwood and Son as official publishers to the committee. All the reports and specifications published by the committee may be had from the official publishers or direct from the offices of the committee, 28 Victoria Street, Westminster.

AT the London Institution on Monday Sir John Gunn delivered his presidential address to the members of the Institute of Marine Engineers. The Denny medal was then presented to Mr. C. W. Barnes for his paper on ship electric lighting. The medal was founded by the late Mr. Peter Denny, of the shipbuilding firm of Denny Brothers.

A CORRESPONDENT in Paris writes that another trial of the steerable balloon *Le Jaune* was made on November 20. According to the readings of the Eiffel Tower, the wind was blowing S.S.W. with a mean velocity of 10 metres a second when *Le Jaune* left Champ de Mars at 11.25 a.m., and in a few seconds the balloon rose to a height of about 100 metres. At first the helm alone was used, and then one of the screws. The balloon soon took the direction of Chalais-Meudon, reaching its destination at 11.52 a.m.

IN moving the adoption of the report of the Government Department Committee appointed last year to inquire into the constitution, powers, and duties of the curiously named Board of Manufactures, at the recent annual meeting of the Royal Scottish Geographical Society, Sir John Murray urged the claims of science to more generous treatment. The recommendations of the committee include the reconstruction of the Board of Manufactures and the adoption of a variety of expedients to ensure better instruction in art and the improvement of the art galleries in Edinburgh. During the course of his remarks Sir John Murray said he would have liked a recommendation that certain of the buildings administered by the Board should be devoted to the purposes of science. Arrangements could, he said, be easily made for housing the Royal Geographical Society and other scientific societies, and they should all unite to secure the Edinburgh Royal Institution for science.

A DEPUTATION from the Institution of Electrical Engineers was received at Windsor on Friday last by the King of Italy and presented an address. The deputation consisted of Mr. Robert Kaye Gray, president, Lieut.-Colonel R. E. Crompton, Sir H. Mance, Dr. J. W. Swan, F.R.S., and Prof. Silvanus P. Thompson, F.R.S., accompanied by Mr. W. G. McMillan, secretary of the Institution. Telegrams were dispatched the same evening to the Associazione Elettrotecnica Italiana and to the Milan section of the Associazione, and the following replies were received from them:—"Most sensible to the feelings that inspired your kind telegram. I thank the Institution of Electrical Engineers for the new proof of sympathy, and return most hearty greetings in the name of the Associazione Elettrotecnica Italiana."—(Sd.) Ascoli. "Homage added by Institution of Electrical Engineers to enthusiastic reception to our King by all England was learned with grateful feelings by Milan Section Associazione Elettrotecnica Italiana as a new token of friendship binding Scientific bodies of the two Countries."—(Sd.) Bertini.

THE Berlin correspondent of the *Times* reports that at a meeting of the German Society of Naval Architecture held on November 20 in the technical college at Charlottenburg, a paper was read by Geheimrath Riedler on the revolutionary effect of the invention of the steam turbine upon the future of steam power. A great revolution in steam power was in progress, and the lecturer regretted that Germany lagged far behind in the adoption and development of the new motor. In a paper on the uses of the telephone for naval purposes, Herr D. Zopke, the Government constructor, gave an account of an adaptation of the so-called "stentor microphone" by means of which not only could commands be conveyed to all parts of a vessel, but the men working six guns could be directed simultaneously by a single officer. He discussed experiments made with the microphone with the object of making it give warning of the approach of hostile ships, and concluded by giving some details of the progress which had been made in Germany in the attempts to solve the problem of wireless telephony.

REFERRING to Mr. Douglas Archibald's letter on Bruckner's weather cycle, mentioned in last week's NATURE (p. 62), Dr. H. R. Mill remarks in the *Times* that the cycle does not fit the sequence of weather so satisfactorily in the British Isles as on the continents, but he urges that there must be some way to reconcile the differences, and that the subject should be taken up by some scientific society. In a letter in Tuesday's *Times* Mr. Archibald explains that according to Bruckner's studies this country happens to lie on an axis of a weather see-saw, so that east Britain alone conforms to the continental law. "Dr. Bruckner shows plainly from the past records of British stations how the law which is found to apply all over the Eurasian continent holds with somewhat diminished intensity over the eastern half of Britain, and then, after disappearing over the neutral territory of west Britain and east and middle Ireland, reappears in its opposite phase over north-west Ireland, in common with the Færöes and Iceland." In conclusion, Mr. Archibald gives the following comparison for Brussels and London to show that the Bruckner oscillation loses little in its passage across the Channel.

Total Excess or Defect of Rainfall in the Period.

	Brussels Inches	London Inches
1826–1840 [1]	− 7·20	− 6·17
1841–1855	+ 7·16	+ 4·35
1856–1870	−21·25	−11·85
1871–1885	+33·34	+19·65
1886–1902	−25·44	−29·75

[1] For Brussels the period of observation embraces 1833–1901.

WE have received some numbers of the *Journal* of the Meteorological Society of Japan. They contain several valuable papers relating, *e.g.*, to observations in the Inland Sea and North Pacific, articles on the distribution of barometric pressure in Formosa, and reduction tables. At present the text is in Japanese, but it is stated it is intended to insert articles occasionally in English, French or German. This plan will render the *Journal* much more useful to European readers. The Society was founded in 1882, and counts at present more than 200 members.

The International Aëronautical Committee (president, Dr. Hergesell) has discontinued the publication of the preliminary results of the monthly scientific balloon ascents in view of arrangements made for the speedier issue of the discussion of the definitive results. We have received, however, short summaries of the ascents undertaken by the various countries. In August Mr. Alexander's paper balloon, at Bath, attained a height of 13,000 metres. In September Mr. Dines's kite, at Crinan, N.B., reached an altitude of 2250 metres. The greatest height attained during the last three months was 20,000 metres in an unmanned balloon sent up from Strassburg.

In the *Sitzungsberichte* der Physikalisch-medicinischen Societät in Erlangen, Herr Fritz Buchner describes an interesting method of measuring the gradual falling off in the intensity of the phosphorescence of bodies excited by kathode rays. This is effected by an arrangement of rotating films, the photographic impression produced by the phosphorescent body as measured by the polarisation photometer of Martens being taken as the measure of the intensity. The author expresses the opinion that the phosphorescent light is a direct consequence of the combination of the ions produced by the action of the kathode rays to form electrically neutral molecules.

A new anti-tuberculous serum is stated to have been prepared by Dr. Marmorek, of the Pasteur Institute, Paris. By the use of a special culture medium for the tubercle bacillus, a toxin has been obtained with which horses are inoculated, and after repeated doses their blood-serum acquires antitoxic properties. The serum may then be employed for treatment, and many cases are reported to have been benefited by the injections. Dr. Marmorek is well known for his work in connection with the preparation of an anti-streptococcic serum.

In the October number of the *Journal of Hygiene* (vol. iii., No. 4) Drs. Hill and Macleod give an elaborate experimental study of caisson disease and diver's palsy, Dr. Newsholme reviews the action of English public health authorities in regard to tuberculosis, and Dr. Barclay discusses the New Zealand birth- and death-rate. The air of the House of Commons has been subjected to chemical examination by Mr. Butterfield, and to bacteriological examination by Dr. Graham Smith, from which it appears that the air breathed by our legislators is exceptionally pure. Dr. Cropper writes on the occurrence of malaria in places usually free from anopheles, and Dr. Nuttall contributes an obituary notice of the late Prof. Nocard, with portrait and list of his published papers.

In a report to the Home Office, Dr. Haldane gives an account of ankylostomiasis in the Westphalian collieries. This disease, which is due to a parasitic intestinal worm, has, since its introduction in 1895, been spreading considerably, so that in 1902 there were more than thirteen hundred cases in sixty-nine collieries. Official regulations have been drafted in order to stamp out the disease, the chief provisions of which are:—(1) no new hands may be engaged unless proved to be free from infection; (2) in every colliery at least 20 per cent. of the men shall be picked out by a specially instructed doctor, and their dejecta examined microscopically on at least three occasions; (3) any man found to be infected is subjected to a course of treatment, and is not allowed to resume work until completely freed from the worms. In the event of the examination of 20 per cent. of the men showing the mine to be infected, additional measures are taken:—(4) the whole of the men employed underground are examined, and if necessary treated; (5) every man treated is to be re-examined monthly for three months. In addition, regulations have been made for the better sanitation of the mines. The infected men are treated in hospital, and receive sickness allowance during treatment.

A Blue-book containing the official report of the preliminary conference on wireless telegraphy which was held in Berlin last August has just been published. The decisions arrived at were known some time ago, and in September last we summarised the main points in an article in these columns (Nature, vol. lxviii. p. 437). There is little to add to what was then said; the final protocol which was drawn up was signed by the delegates from Germany, Austria, Spain, the United States, France, Hungary and Russia. The delegates of Great Britain and Italy agreed to submit the proposals to their Governments with certain reserves. In the case of Italy the agreements made between the Marconi Co. and the Government greatly limit the power of the Italian Government to adopt the proposals of the conference. In Great Britain the difficulty lies in the fact that the Postmaster-General has no power over telegraphic communications beyond the limits of the territorial waters, and special legislation would therefore be required. In most of the other countries the telegraphy monopoly covers the establishment of wireless telegraph stations. When the proposals of the present conference have been considered by the various Governments a further conference will be held to establish an International Conference.

The third part of Sir C. Le Neve Foster's general report and statistics relating to the output and value of the minerals raised in the United Kingdom, the amount and value of the metals produced, and the exports and imports of minerals, has now been published. This volume deals especially with the output during 1902. The total output of coal was 227,095,042 tons, which is the largest on record; compared with the output of 1901, there is a rise of 8,048,097 tons. We consumed 166,694,908 tons in the United Kingdom, or nearly 4 tons per head of the population. 17,649,137 tons of coal were used in blast furnaces for making pig-iron. The quantity of coal exported, exclusive of coke, patent fuel, and coal shipped for use of steamers engaged in foreign trade, was 43,159,046 tons, an increase of 1,281,965 tons compared with the preceding year. If the quantities shipped for use of steamers engaged in foreign trade are added, the total amount of coal which left our shores was 60,400,134 tons, or about as much as the entire output of the kingdom half a century ago.

In a recent note (October 15, p. 578) on articles in the October number of the *Century Magazine*, the name of the yellow-fever mosquito was inadvertently given as *Culex aeniatus* instead of *Stegomyia fasciata*.

The *Transactions* of the Hull Scientific and Field Naturalists' Club for 1903 contain the article on the birds of Bempton Cliffs of which a special notice has already appeared in our columns. In a note on the dispersal of fresh-water shells by beetles, the Rev. E. P. Blackburn records the capture of several water insects with pisidia clinging to their limbs.

The report of the Albany Museum for 1902 records satisfactory progress on the part of that institution. Special interest attaches to the announcement of the discovery of a small lizard's skull from the Karoo formation, which it is proposed to call *Paliguana whitei*. This is believed to be

the only true lizard from strata of pre-Jurassic age. The specimen is to be described in the first number of a new journal, *Records* of the Albany Museum.

THE National Museum of Dublin was enriched last year by the gift of a very extensive herbarium of Irish plants, collected by the late Mr. Levinge, of Co. Westmeath. In the *Scientific Proceedings* of the Royal Dublin Society Dr. Johnstone and Miss Knowles have published a list of plants, for which the localities furnish new records, whether for the county or for other parts of Ireland.

IN the *Journal of Botany* (November) Dr. Rendle gives a description of the grass *Glyceria festucaeformis*, new to Britain, which was discovered by Mr. Praeger on the north-east coast of Ireland. This is an unexpected locality for a grass which is regarded as a Mediterranean type. In the same journal there appear two lists of mosses and hepatics, the one for Worcestershire recorded by Mr. Bagnall, the other contributed by Canon Lett of collections made in South Donegal.

IN a *Bulletin* issued by the U.S. Department of Agriculture which deals with the diminished flow of the Rock River, Mr. F. G. Schwarz discusses the question how far the water supply of a river is affected by drainage and deforestation. He contends that the actual diminution in amount is unimportant as compared with the resulting fluctuations in the flow of water, especially where the melting snow provides an appreciable source of the supply. As a remedy it is suggested that, in addition to increasing the area of forest, it would probably pay, where the land is valuable, to construct artificial reservoirs for regulating the supply of water.

THE complex series of movements which are carried out by the flowers of *Sparmannia africana*, a well-known greenhouse shrub, from the opening of the buds to the setting of the fruit has been carefully studied by Mrs. D. H. Scott, and is described in the *Annals of Botany*. In the latter part of the paper the writer gives an account of experiments which were carried out in order to show these movements by means of a kinematograph, and in which success was ultimately attained by the use of an instrument called after the maker the Kammatograph. In the Kammatograph, by means of eccentric rotation, exposures are made of successive portions of a film coated on a glass disc, so that a series of spirally arranged negatives is obtained.

THE latest Rationalist Press Association reprints, published by Messrs. Watts and Co., are John Stuart Mill's "On Liberty" and "Haeckel's Critics Answered," by Mr. Joseph McCabe. Both are published at sixpence.

MESSRS. MACMILLAN AND CO., LTD., have published in their sixpenny series "Essays Ethical and Political," by the late Prof. Huxley. The Romanes lecture delivered in 1893 on "Evolution and Ethics" is included, together with the Prolegomena written in the following year.

A NEW edition of Mr. G. Hale Puckle's "Elementary Treatise on Conic Sections and Algebraic Geometry" has been published by Messrs. Macmillan and Co., Ltd., at 7*s*. 6*d*. Alterations in the treatment of the general equation of the second degree have been made, and more simple methods of reduction and of finding the foci, eccentricities and axes are given.

WE have received the fifth half-volume of the "Natural History of Animals," by Prof. J. R. Ainsworth Davis, now being published by the Gresham Publishing Company. Previous volumes of the work have already been reviewed in these columns; the present part deals fully with animal movement in eleven chapters, running to 280 pages, and is illustrated by nearly 250 figures and three coloured plates.

THE second volume of Prof. H. Pellat's "Cours d'Électricité" has been published by M. Gauthier-Villars, of Paris, at 18 francs. The publication of the first volume, which deals with electrostatics, Ohm's law, and thermo-electricity, was announced in these columns in 1901. The present volume is concerned with electrodynamics, magnetism, the phenomena of induction, electromotors, electric oscillations, electromagnetic measurements, and similar subjects. A third volume, yet to be published, will complete the course, and will discuss electrolysis, electrocapillarity, and associated subjects.

THE additions to the Zoological Society's Gardens during the past week include a Campbell's Monkey (*Cercopithecus campbelli*) from West Africa, presented by Mr. J. F. Purser; a Macaque Monkey (*Macacus cynomolgus*, var.) from India, two African Brush-tailed Porcupines (*Atherura africana*) from West Africa, a Rose-Hill Parrakeet (*Platycercus eximius*) from Australia, deposited.

OUR ASTRONOMICAL COLUMN.

SOLAR PHENOMENA AND MAGNETIC STORMS.—In a communication presented to the Paris Academy of Sciences, M. Quenisset directs attention to the fact that, whilst the passage of a large group of sun-spots across the sun's central meridian on October 31 coincided with a terrestrial magnetic storm of exceptional activity, the passage of a much larger group on October 11 was marked by a very faint perturbation of the magnets. In explanation of this apparent anomaly he points out that the smaller group of spots was surrounded by an immense tract of faculæ, so bright that it was found possible to photograph them by the ordinary method, even when they were on the sun's central meridian, whilst scarcely any faculæ attended the larger and earlier group. From this fact M. Quenisset arrives at the conclusion, which is now becoming generally accepted, that it is the prominences and faculæ on the solar surface rather than the spots which are so closely related to terrestrial phenomena, and suggests that the monochromatic photographs of the solar surface obtained by the Hale-Deslandres method, such as are now being taken at Yerkes, South Kensington, and Meudon, will provide valuable data for the discussion of the inter-relation of solar and terrestrial phenomena (*Comptes rendus*, November 9).

OBSERVATIONS OF JUPITER.—In the November number of the *Bulletin* de la Société astronomique de France, M. Ch. Lukacs, of Budapest, publishes the results of his observations of Jovian phenomena during 1902; the following are the principal conclusions derived from the observations:—(1) The Red Spot has totally disappeared except at its eastern extremity; (2) the southern equatorial band shows remarkable activity in its northern parts; (3) the equatorial band, formerly the scene of the greatest activity of Jupiter's atmospheric forces, has now become absolutely uniform; (4) the northern equatorial band is growing gradually fainter from the south towards the north; (5) the south temperate band presents a curious depression just above the eastern extremity of the Great Red Spot, and, on August 6, two very sharply defined deviations in the course of this band were observed, the one at 125°, the other at 175° of Jovian longitude; these deviations were similar to those observed by the late Prof. Keeler on August 28, 1900; (6) the colour of the equatorial bands was a brownish ochre; the zones, generally, appeared to be of a whitish yellow, with the exception of the tropical zones, which were white, and the polar zones, which had a grey tinge mixed with yellow.

In his communication M. Lukacs gives the details of his individual observations and twelve excellent drawings of the planet as it appeared on various occasions during 1902.

THE FORMS OF THE RING AND DUMB-BELL NEBULAS.—In a recent number (539) of the *Astronomical Journal* Prof. J. M. Schaeberle stated that by using a short focus reflector he had obtained photographs of the Ring nebula which plainly showed that this object had a clockwise spiral form. In several fainter photographs obtained since, where faint nebulosities are shown only at the extremities of the major axis of the ellipse, he noticed a decided similitude in shape to the dumb-bell nebula in Vulpecula, and was induced to photograph the latter object in order to see if that, too, was a spiral; the photographs obtained show that it is, but in this case the spiral is counter-clockwise.

From these photographs of the two objects Prof. Schaeberle concludes that they were formed, in each case, by simultaneous emissions of matter from a central mass, several streams leaving the parent body in diametrically opposite directions, and with various velocities, at the same time and forming inner and outer streams of which the inner would travel round the central body several times while the outer streams were making one revolution; where these two streams meet and are superimposed, the nebulosity is much brighter, and exhibits the forms usually attributed to these objects. If we suppose that the outer boundary of the nebula, as it is usually seen, represents the exterior limit of the inner streams, and that the general arrangement of the nebula is due to gravitational forces, this theory demands that the outer streams should extend much further than is generally shown on photographs, and, in proof of this, Prof. Schaeberle has obtained photographs which show that various exterior nebulosities, and many of the adjacent faint stars, are probably part of one huge structure of which the Ring nebula is only the central condensation.

Similar proofs have been obtained to show that the formation of the Dumb-bell nebula may be explained by the same hypothesis, for on several photographs it is plainly seen that various wisps of nebulosity, which are concave towards the Dumb-bell and include several streams of faint stars, are, with the Dumb-bell, probably parts of the same original mass (*Astronomical Journal*, No. 547).

BIOLOGICAL WORK IN SOUTH AFRICA.

THE issue of the report of the Government biologist (Dr. J. D. F. Gilchrist) of the Cape of Good Hope for 1901 affords a favourable opportunity for directing attention to the energy with which biological investigations are being carried on in South Africa. Several volumes of the excellent "Fauna of South Africa," under the editorship and part authorship of Mr. W. L. Sclater, director of the Cape Town Museum, have from time to time been reviewed in our columns, where reference has likewise been made to various papers in *Marine Investigations in South Africa*, the *Annals* of the South African Museum, and other local publications. From some of these notes we venture to repeat extracts on the present occasion. It may be added that, apart from local publications, Mr. O. Thomas, of the British Museum, in papers published in the *Annals and Magazine of Natural History*, has been able to increase our knowledge of the mammals of South Africa, thanks to collections sent to this country by Colonel Slogget, R.A.M.C.

The Government biologist commences his report with an account of the trawling operations recently undertaken off the Natal coast at the request of the Government of that flourishing colony. The Natal coast is by no means promising for trawling, and as much money had been spent on previous occasions with no good results, and the recent trip proved equally unsatisfactory, the Government was advised to devote its attention to the development of line fishing, and to rely on the Cape trawling-grounds for its supply of soles. During the operations many new forms of marine life were procured, which are being investigated by specialists. On the return of the surveying vessel to Cape waters, a new trawling-ground was discovered, which promises to yield a valuable supply of food-fish.

As regards inland-fisheries, breeding operations have been seriously hampered owing to the hindrances inseparable from the institution of martial law in the country, while an unfortunate case of poisoning did not tend to mend matters. Nevertheless, the director is able to report that the rainbow-trout are in a very satisfactory condition, and that carp are likewise flourishing.

The report includes a reprint from *Marine Investigations* of Mr. R. Kirkpatrick's first paper on the sponges obtained during the Natal and Cape cruises. The third part of this contribution (*Marine Investigations*, vol. ii. part iii.) is just to hand. Several genera and many species are described as new, and the author directs attention to a notable resemblance between the sponge-fauna of South Africa and that of Australia.

A second paper reproduced in Dr. Gilchrist's report is one by Mr. G. B. Sowerby on South African molluscs, in which is described a new species of Volutilithes, making the third existing representative of that genus, which was first described from the Barton Clay. Another contribution to this subject by the same author appears in vol. ii. of *Marine Investigations*, where a number of new forms of Pleurotoma and Conus, as well as representatives of other genera, are described.

In the same volume the South African corals of the genus Flabellum receive attention at the hands of Mr. J. S. Gardiner who pays special attention to the anatomy and development of these organisms, and emphasises the importance of studying the polyp as well as the corallum if we hope to gain any real idea of their true relationships.

This volume of *Marine Investigations* also contains some valuable notes by Dr. Gilchrist on the development of South African fishes. These notes have an important bearing on certain disputed points connected with the Cape fisheries. Many fishermen urge, for instance, that the spawn of several of the commoner food-fishes is developed on or near the sea-bottom, and is, in consequence, seriously damaged by trawling. To this the author replies that, since in northern waters it has been demonstrated that only one valuable food-fish, the herring, has deep-lying spawn, and since the Cape seas are the home of only a small species of herring of little or no commercial value, it is probable that the damage done by trawling in South African waters has been overestimated.

Under the title of "Rhynchotal Miscellanea," Mr. W. L. Distant, in the *Annals* of the South African Museum (vol. ii. pt. ix. art. 12 and vol. iii. pt. ii. art. 3), publishes a series of notes on the bugs of the country, with descriptions of some new genera and a large number of new species.

In vol. iii., part iii., of the same publication, Mr. G. A. Boulenger describes six new forms of perch-like fishes from the Natal coast, all of which are illustrated in well executed plates, and belong to previously known generic types.

Part iv. art. 5 of the same volume is devoted to descriptions by Dr. W. F. Purcell of new spiders from South Africa belonging to five families.

We must likewise refer to a communication in the *Agricultural Journal* of the Cape of Good Hope for October last, in which the Government entomologist, Mr. C. P. Lounsbury, records an important discovery in regard to the propagation of the South African sheep and goat disease known as "heartwater." The bont-tick has been found to be the only medium of spreading the disease. A single specimen, if fed on a heartwater-sick animal as a larva or "seed" tick, is capable of transmitting the fatal malady. An animal pastured on veld infested by tick may drop thousands of larvæ during its illness, and thus serve for the extermination of a flock. The mortality amongst flocks brought to the coast where the tick is abundant is thus explained. Pathogenic larvæ retain their dangerous character until adult. They may take their second feeding on an ox or a non-susceptible goat, and in the final stage get on to a susceptible sheep or goat and give it fever. On the other hand, the disease appears non-transmissible through the egg-stage, and the species is normally non-pathogenic in all stages. A farm may be infested with bont-tick, yet be free from heartwater. Since the other common species are innocuous, it is hoped that by keeping down the bont-tick the disease may be stamped out.

By no means the least important memoir in the series before us is one by Mr. A. C. Seward on the fossil floras of Cape Colony, forming part i. art. 1 of the fourth volume of the *Annals*. The first section deals with the flora of the Uitenhage series, which is regarded as of Wealden rather than of Jurassic age. The Stormberg, or upper

division of the Karu, flora, on the other hand, is classed as Rhætic, while the Ecca, or lower Karu, flora is identified with some part of the Permo-Carboniferous. The latter conclusion, it may be mentioned, is rendered practically certain by the recent discovery in Kashmir of Glossopteris below marine Permian strata, as recorded in the report of the Geological Survey of India for 1902–3. The occurrence in the Ecca beds of Vereeniging of Sigillaria and other European Carboniferous types points to a closer connection between the South African Glossopteris flora and the Carboniferous flora of the northern hemisphere than exists between the latter and the Glossopteris flora of the Lower Gondwanas of India. The Ecca beds of Vereeniging appear to be the equivalents of the Karharbari beds of the Gondwanas. Finally, although deprecating a precise identification, Mr. Seward is of opinion that the Witteberg flora is probably Carboniferous or Devonian more likely the latter than the former.

That so much good work—both strictly scientific and economic—should have been accomplished during and so soon after a great war is a hopeful sign for the future of South African biology. R. L.

EXPERIMENTS ON WHEAT.

WITHIN the last few years it has gradually been recognised that, although our wheat-fields produce a large bulk of grain, it is, if used alone, unsuitable for the manufacture of the light white bread now generally demanded. In consequence, increasing quantities of the harder and more suitable wheats grown in Canada, the United States and other countries are imported yearly, and the price of the inferior home-grown grain has fallen considerably. More or less concurrently with this greatly improved methods of milling have come into vogue, and the farmer, perhaps not unnaturally, associates the two facts, and all too frequently blames the miller for his reduced margin of profit. A little closer examination of this complicated problem shows that the tendency for the last thirty years or so has been for the yield per acre of grain to rise, and the quality, as estimated by the percentage of gluten present, to fall.[1]

Now in some way or other, precisely how we do not know, the capacity of wheat to yield a strong flour, or its "quality," is bound up in this mysterious mixture of proteids grouped together as gluten, so that if the blame must be apportioned, it rests on those who injudiciously selected wheats for cropping power in preference to quality. Meanwhile, such fine old varieties as Golden Drop, Red Lammas, and Nursery wheats are steadily being driven out of cultivation by varieties slightly superior in yield, but far poorer in quality.

The great importance of making the most of our home wheat-supply has been insisted on time after time by the National Association of British and Irish Millers, and one of the methods they have suggested is to raise improved strains of these good varieties, either by hybridising or by selection. Experiments along these lines have been carried out for the last three seasons by the Cambridge University Department of Agriculture. In the first place wheats known to yield a good quality grain have been crossed together with the object of finding more vigorous races among the progeny of the hybrids. Further, varieties selected from a collection of several hundreds for possessing such characters as a strong, resilient straw, a short period of maturation, and freedom from various diseases, have also been used as parent wheats.

So far it is early to predict any results of technical value, but a number of results of scientific interest have already been arrived at in connection with Mendel's laws of inheritance. The flowers of wheat being autogamous are specially advantageous for such work, as Spielman's careful researches on wheat-breeding, carried out without any previous knowledge of Mendel's work, have shown. Spielman has already recognised that lax ears, the lack of awns, velvety chaff, and red colour are dominant characters, while dense ears, the presence of awns, glabrous chaff and white colour are the corresponding recessive characters.

These results have already been amply confirmed.

Thus from crosses between beardless and bearded wheats the resulting hybrids have invariably shown the beardless character, while their progeny have consisted of beardless and bearded forms in the proportion of three to one. Similar results have been obtained on crossing lax and dense eared races, rough and smooth chaffed, and red and white, though in the last case it has so far been impossible, owing to bad ripening, to distinguish clearly enough between red and white chaff to establish their proportions.

At the same time it has been shown that the sharply keeled glumes found in *Triticum turgidum, e.g.* are dominant over the glumes with rounded bases occurring commonly in the varieties of *T. vulgare,* that the grey colour of glumes and paleæ is dominant over red and white, that broad leaves are dominant over narrow, and rough ones over smooth, that certain groups of bristles on the ridges of the stem which distinguish some varieties are dominant over the ridges without bristles, and that hollow stems are dominant over pithy stems. With regard to grain characters, the long and narrow type is dominant over the short and round, and the red over white. At the same time certain complications have been met with which will entail further investigation. Thus the rough-chaffed grey Rivet's wheat, when crossed with a smooth-chaffed white or red wheat, gives hybrids which vary considerably both in the roughness and colour of the chaff, some being almost glabrous and showing decidedly the red or white colour as well as the grey. The same impure dominance of the rough chaff and colour is found in the following generation. Where other rough-chaffed wheats have been made use of in the place of Rivet wheat though this character has been purely dominant.

Further, particularly among the progeny of the hybrids, there is a marked tendency for the various characters to become intensified. Medium lax, for instance, becomes very lax, the grey colour becomes almost black, and the red a deep brown. At the same time, unexpected forms appear in this generation showing characters unrepresented in either parent. The commonest of these, so far, has been a spelt-like wheat with peculiarly lax ears, thick glumes, and the typically closed spikelets of *T. spelta.* Many of these exceptional forms are sterile—probably owing to imperfectly developed pollen.

These botanical characteristics are, however, of little importance technically, the farmer and miller being concerned chiefly with the quality, yield, hardiness, time of ripening, susceptibility to disease, &c., characteristics, at present practically unexamined, which one might term "constitutional."

The quality of the grain can, to a certain extent, be judged by the hardness and translucency of its endosperm, the poor starchy grain being soft and opaque. Accepting this as a guide, then, good quality is a dominant character, at all events so far as an examination of the first generation of the hybrids goes. The late ripening habit is also dominant over the early ripening habit. As an example, *T. Polonicum,* ripening early in August when sown about the middle of March, was crossed with Rivet wheat ripening late in August when autumn sown. The hybrid grains were sown on March 15, and produced plants which ripened their grain about the middle of September—simultaneously with Rivet wheat sown on the same date.

Experiments on the susceptibility to disease are also being carried out. This point is being investigated both with rusts and mildew, the two serious wheat diseases, inasmuch as they are untreatable. For the purpose of the experiment, in 1901 Michigan Bronze and a wheat with the Michigan Bronze strain in it, viz. Red King, both liable to rust, were crossed with Rivet wheat, which is practically immune. Reciprocal crosses were made in each case. The following year the hybrids were the most badly rusted plants among the experimental plots, and there was nothing to choose between the plants with Rivet wheat as male or female. Incidentally, then, it might appear to anyone who accepted Eriksson's views that in the case of Rivet wheat ♀ × Red King or Michigan Bronze ♂, the so-called "mycoplasma" had reached the hybrid grain by way of

[1] The figures are set out in detail in Girard and Lindet's "Le Froment et sa Mouture," p. 101. (Paris, 1903.)

the generative nuclei. But is such an interpretation possible? I think not.

On harvesting the plants the grain was found to be badly shrivelled, the Michigan Bronze crosses only producing three grains, none of which germinated. From about three hundred grains of the Rivet and Red King crosses, two hundred and sixty plants were raised. The rust appeared on these as early as March 16, and by June 15 many plants were orange-coloured even on the highest leaves. On counting out the plot, 78 plants were found to be free from disease, 118 were slightly infected, and 64 were badly attacked. By June 29 the epidemic seemed to be at its height, and a second count showed that the number of disease-free plants was reduced to 64, while 195 were infected, for the most part badly.[1]

These figures seem to be too close an approximation to the Mendelian ratio of 1 : 3 to be a mere accident, especially when taken in conjunction with the results of the first generation. The susceptibility of wheat to the attacks of rust is therefore a definite Mendelian character.

If further researches should show that this capacity for resisting the attacks of disease-producing fungi is in reality a tangible characteristic, the plant-breeder, at all events, will have definite lines to go upon in attempting to solve one of our most important agricultural problems, namely, that of producing disease-resisting strains.

R. H. BIFFEN.

[1] One plant overlooked.

PROBABLE ERROR IN VITAL STATISTICS.

A PAPER on "The Degree of Accuracy of Statistical Data," by Mr. Carl C. Engberg, has been published by the University of Nebraska. "This paper," Mr. Engberg tells us, "is written as a protest against the unnecessary refinement of statistical computations as carried out by the biometricians of to-day." Mr. Engberg complains that the more "prominent biometricians" have worked with five or six figures when they might have worked with three or four with equally good results. He illustrates this by comparing Prof. Pearson's work on enteric fever, published in 1894, with a revision of it by himself using only three places of decimals. He considers that the one is as good as the other. He does not, however, apply the test for relative goodness of fit of observation to theory—*Phil. Mag.*, July, 1900—but discards it without examining the analysis by which it is reached, on the basis of a paradox that he has not been able to see through. He appears to dislike the test because if 16,000 observations are distributed in the same proportions in n groups as 1000 observations the former distribution shows a lower probability for the fit than the latter, if the same curve be used in both cases. This, however, must be right. 16,000 observations should give a result nearer a smooth curve than 1000. The percentage error has been discarded for years by trained biometricians; it was merely a temporary *modus vivendi*.

As to the use of a greater or less number of decimal places, to those who work with mechanical calculators the number is practically indifferent, and to trained computators even a 7 or 10 figure table of logarithms is hardly slower in use than a 4 or 5 figure table. But are the decimal places when reached worth having? Very often not, very often they are. Mr. Engberg seems quite incapable of distinguishing between the two classes of cases. The only means of testing is to consider the probable errors of the results. The theory of the probable errors of the constants of frequency curves was not given until 1898, and it was not possible to say in 1894 how many places of decimals were or were not necessary. Mr. Engberg appears to think that because vital statistics are tabled to one or even four year units, it is impossible to ascertain the values of constants to two or three decimal places of those units. He states, vaguely, that "the constants cannot be more accurate than the data upon which they are based." He might well have asked the American actuaries for their views on this point! Practical men do not work to 6 or 10 figures for the mere pleasure of it, and in the particular case cited by Mr. Engberg—"Makeham's c"—we have a constant which has often to be raised to the fiftieth power! Does Mr. Engberg believe that the mean age at death of a population of several millions, classified solely by year of age at death, cannot be found to less than the rough year which is the basis of the grouping?

Mr. Engberg says that his "paper has not been written in a fault-finding spirit by a detractor of the new science of biometry, but by a teacher of the science." It seems a pity that Mr. Engberg should not have studied either the history or literature of the science he is teaching, or, apparently, have received a training in mathematical statistics. In the former case he would have known that the method he suggests on p. 9 has been long in use (Yule, *Proceedings* of Royal Statistical Society, vol. lx., part iv., 1897), and the inner meaning of tables of powers for testing the *last* column of high moment tables would have been obvious to him. In the latter case he would have made a valid criticism of over-many decimal places by simply showing that they gave results beyond the probable error of the constant involved, or did not improve the goodness of fit as tested by a legitimate method. We are doubtful whether the growing practice of appointing teachers of biometry in the American universities without preliminary training is really helping the science forward. It leads, it is true, to a multitude of biometric papers, but very few of these are of permanent scientific value.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—On Thursday, November 19, an election took place of great importance in relation to the advancement of the study of mental science in Oxford—that of Dr. W. MacDougall to the readership in psychology founded some years ago by Mr. Wilde. The first reader was Mr. Stout, the well-known editor of *Mind*, who last summer resigned the Oxford appointment for a professorship at St. Andrews. His successor will no doubt follow in Mr. Stout's footsteps, but those who appreciate the value of the experimental method in psychology confidently anticipate that opportunity will now be given for this study in Oxford. Dr. MacDougall has himself approached the subject from the experimental side, and is the author of very important researches on the physiology of the nervous system, among which those relating to the theory of colour vision may be taken as examples. As a member of the Cambridge Anthropological Expedition to Torres Straits and Borneo, he conducted experimental researches on the mental processes of savages, which afford substantial evidence of his power as an investigator. When to this it is added that he is no less a master of the older methods than of the new, and is regarded as a man of power alike by physiologists and by philosophers, the university may well be congratulated on so valuable an accession to its intellectual forces. Against any regret that may be felt that the new reader is not an Oxford man, the fact may be set off that one of the most successful and influential of American experimental psychologists—Prof. Titchener—received his training in both sides of the subject at Oxford.

CAMBRIDGE.—Dr. Hobson, F.R.S., has been appointed the first Stokes lecturer, and Dr. Baker, F.R.S., the first Cayley lecturer, in mathematics.

An Isaac Newton Studentship of 200*l.* a year for three years, for research in astronomy and astronomical physics, will be vacant in the Lent term, 1904. Candidates must be bachelors of arts under twenty-five years of age. Applications are to be sent to the Vice-Chancellor by January 26.

The degree of D.Litt. is to be conferred *honoris causa* on Prof. Théophile Homolle, member of the Institute of France, director of the French School of Athens.

Prof. Woodhead, Mr. J. E. Purvis, Dr. Tatham, Dr. Lane Notter, and Dr. R. D. Sweeting have been appointed examiners in State medicine for the diploma in public health.

The scheme for the establishment of a geographical school and the institution of a special examination in geography and a diploma in geography will be submitted to Senate for adoption on December 5.

PROF. WILLIAM F. DURAND, professor of marine engineering, has been appointed acting director of Sibley College, Cornell University, in succession to the late Prof. Thurston.

DR. MORRIS W. TRAVERS has been appointed professor of chemistry in University College, Bristol, in succession to Prof. Sydney Young, F.R.S. Dr. F. E. Francis, lecturer in chemistry, has been promoted to the rank of assistant professor in the college.

SPEAKING at Limerick last week in distributing prizes to the pupils of the Municipal Technical, Science and Art Schools, Sir Horace Plunkett remarked that the whole country had now taken up the work of technical education with a quickness, receptivity, and responsiveness which he was told by educational experts had not been witnessed in any country under similar economic conditions, and in so short a time. There was now scarcely a corner of Ireland where the people were not showing an anxiety and practical interest to take up a scheme which had been introduced under the auspices of the Department of Agriculture and Technical Instruction.

IN the course of an address at Liverpool on Saturday last Sir Philip Magnus remarked that our very existence as a nation depended upon our continued educational advance. There was a startling contrast between the liberal expenditure in America and Germany upon specialised university research and the small sums spent here. This country had little to learn from the method of teaching in American schools, but what we could and must learn if we were to recover lost ground was a changed attitude towards education itself. Few manufacturers in this country yet realised the economy and industrial advantages of attaching to their works intelligence departments staffed with scientific experts. He was glad to say, however, even in this respect the outlook was improving, and there were many signs of brighter days in store.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 19.—"The Sensation of Light produced by Radium Rays, and its Relation to the Visual Purple." By W. B. **Hardy** and H. K. **Anderson**.

When a few milligrammes of radium bromide are brought near the head in the dark a sensation of diffuse light is produced. The authors find that this is not due to any direct response on the part of the retina, the optic nerve, or the brain, but to a fluorescence of the tissues of the eyeball, notably of the lens and of the retina itself, excited by the β and γ rays.

The visual purple of the retina is not bleached by any of the radium rays.

The authors point out in passing the peculiarly high opacity of the eyelid to the rays, as compared with the skin of other parts of the body.

Physical Society, November 13.—Dr. R. T. Glazebrook, F.R.S., president, in the chair.—Sir Oliver J. **Lodge** read a paper on means for electrifying the atmosphere on a large scale. Twenty years ago the author was engaged with Mr. J. W. Clark on an investigation of the dark spaces seen near hot bodies placed in illuminated smoke. The existence of these dust-free spaces was discovered by Tyndall, and the phenomenon had been investigated by Lord Rayleigh. Tyndall worked with high temperatures, and attributed the effect to the burning of the dust near the hot body. Such, however, cannot be the case, as the spaces exist when inorganic dust, such as oxide of magnesium, is used. The conclusion at which Messrs. Lodge and Clark arrived (see *Phil. Mag.*, 1884) was that the result was due to an aërial bombardment from the hot wire which drove the particles away, and they tried the effect of electrifying the hot body to see if there was any modification of the dark space. A new phenomenon was discovered, the whole of the dust being driven to the sides of the containing vessel. This experiment was shown by the author at the British Association meeting in Montreal in 1884, and subsequently, on a larger scale, at the Royal Institution. In the latter experiment two pieces of wire gauze, connected to the terminals of an electric machine, were placed opposite each other in a smoke-filled chamber, through which a current of smoke was slowly passing. Upon electrifying the plates the smoke ceased passing, the dust particles cohered, hovered in the air, and were either driven to the sides of the chamber or fell to the bottom. In the case of mist, electrification of steam in a bell jar converted it into fine rain. It seems therefore possible that rain might be produced by the electrification of a cloud. Sir Oliver Lodge has tried at Liverpool to disperse fogs by discharging electricity into them. For this purpose a large mast was erected on the roof of the University College buildings. It terminated in a bundle of points, to which electricity was conveyed from a Wimshurst machine by a wire supported by specially constructed insulators. In order to drive electricity from a point far removed from a surface a high potential is necessary, and sometimes a large gas flame was used to supplement the points. Upon one occasion the discharge of electricity from the flame was sufficient to keep a clear space of 50 or 60 yards radius in a dense fog. The author had hoped to induce the Mersey Dock Board to try the principle on a large scale, having a series of positive discharges on one side of the river and a series of negative discharges on the other; but he felt a certain reluctance in recommending the method to practical men so long as it was necessary to derive the current from a Wimshurst machine. A dynamo would be a more suitable generator if it were possible to get a sufficiently high potential. The way out of the difficulty is to rectify a high-tension alternating current, and Sir Oliver Lodge has for some time been considering the possibility of doing this by utilising Cooper-Hewitt mercury lamps. A study of these lamps has led him to believe that their rectifying power is much assisted by the outside metallic coating which surrounds the mercury electrode, and which is connected to the positive terminal of the lamp. In order to rectify an alternating discharge, four lamps are so arranged in the form of a quadrilateral that, when the leads from the terminals of an alternating transformer are connected to two opposite corners, two unidirectional currents are obtained from the other corners. Experiments have been made at Birmingham by sending the current from a high-frequency alternator (3000 ~ per sec.) through the primary of an induction-coil and connecting the terminals of the secondary to the rectifiers. The length of the rectified spark can be increased by putting a number of lamps in series in each arm of the quadrilateral arrangement. Sir Oliver Lodge performed an experiment at the meeting to show the dissipation of fog by electrification. The current from an alternator was passed through the primary of a coil and the terminals of the secondary connected to the rectifiers, twelve lamps in all, three in series in each arm. This arrangement is capable of giving a rectified spark 2 or 3 inches long, the unidirectional nature of which can be proved by passing it through a Crookes or a Röntgen tube. Some magnesium wire having been burnt under a large bell jar to fill it with a cloud of magnesium oxide, the jar was then illuminated by the light from an electric lamp. Passing through the base-piece upon which the bell-jar was placed was a conductor which terminated in a point inside the jar. When the terminals between which the rectified discharge was passing were separated and the other end of this conductor was joined to one of them, the electricity streaming from the point into the clouded atmosphere caused an immediate deposition of the magnesium oxide.—Sir Oliver **Lodge** also described an arrangement for driving mercury pumps, designed by Mr. B. Davies and himself.

Chemical Society, November 5.—Prof. W. A. Tilden, F.R.S., president, in the chair.—The following papers were read:—The reduction of hydrazoic acid, by Mr. W. T. **Cooke**. The products were hydrazine and ammonia in place of the expected cyclic nitrogen hydride.—Preliminary note on the viscosity of liquid mixtures, by Messrs. A. E. **Dunstan** and W. H. C. **Jemmett**. The viscosity curve of a mixture of two non-associated liquids is a straight line, of a non-associated with an associated liquid, a line convex to the axes, and of two associated liquids, a line concave to the axes.—Contribution to the study of the reactions of hydrogen peroxide, by Mr. J. **McLachlan**. The evolution of oxygen induced by the addition of solutions of hydrogen peroxide to acidified solutions of potassium

bichromate or permanganate is not quantitative. Manganese dioxide reacts with hydrogen peroxide only in presence of sulphuric acid, and even then the reaction is incomplete.—The constitution of certain silicates, by Mr. C. **Simmonds.** The results obtained in a series of reduction experiments made on metallic silicates indicate that in complex silicates the silicon atoms are attached to each other, and each to two atoms of oxygen, the unappropriated oxygen atoms being those by which the metallic oxides are attached to the silica complex.—Constitution of chrysophanic acid and of emodin, by Messrs. H. A. D. **Jowett** and C. E. **Potter.** Chrysophanic acid is shown to be 5 : 8-dihydroxy-1-methylanthraquinone, and emodin either 2 : 5 : 8- or 3 : 5 : 8-trihydroxy-1-methylanthraquinone.—Conductivity of substances dissolved in certain liquefied gases, by Messrs. B. D. **Steele** and D. **McIntosh.** The conductivities of solutions of a number of substances in liquefied hydrogen chloride, bromide, iodide, sulphide, and phosphide have been determined.—The behaviour of metallic oxides towards fused boric anhydride, by Messrs. C. H. **Burgess** and A. **Holt.**—Note on some reactions of vanadium tetrachloride, by Mr. B. D. **Steele.** A description of the results obtained by the use of vanadium tetrachloride as a chlorinating and condensating agent in the synthesis of organic compounds.—Studies on comparative cryoscopy, i., the fatty acids and their derivatives in phenol solution, by, Mr. P. W. **Robertson.** It is shown that the rate of association for fatty acids (normal) rises and falls as the series is ascended, and is influenced both by the nature and position of a substituent.—Vapour pressures of sulphuric acid solutions, by Mr. B. C. **Burt.**—Additive compounds of *sym*-trinitrobenzene and alkylated arylamines, by Messrs. H. **Hibbert** and J. J. **Sudborough.**—Interaction between chloric and hydriodic acids, by Mr. J. **McCrae.** A study of this reaction, and especially of the rate at which it progresses.—3 : 5-Dichloro-1 : 1 : 2-trimethyl-$\Delta^{2 \cdot 4}$-dihydrobenzene. A correction, by Mr. A. W. **Crossley.** This compound is now shown to be the corresponding derivative of unreduced benzene.—The estimation of hydroxylamine, by Messrs. H. O. **Jones** and F. W. **Carpenter.** The method is based on the reduction of alkaline copper solutions by hydroxylamine.—A study of the isomerism and optical activity of quinquevalent nitrogen compounds, by Mr. H. O. **Jones.** A number of derivatives of the type N.R.R′R″X have been prepared, but from these no optically active isomerides could be obtained.—The influence of various substituents on the optical activity of tartramide, by Messrs. P. F. **Frankland** and A. **Slator.**—The influence of cyclic radicles on optical activity; tartaric-*ar*- and *ac*-tetrahydro-β-naphthylamides, furfurylamide and piperidide, by Messrs. P. F. **Frankland** and E. **Ormerod.** Part of a systematic examination of the relationship between rotation and chemical constitution of optically active substances.—The rotatory power of maldiamide, maldi-*n*-propylamide, and maldibenzylamide, by Mr. J. **McCrae.**—Further experiments with phosphorus sesquisulphide, by Mr. E. G. **Clayton.** The results of the application of Mitscherlich's test to specimens of phosphorus sesquisulphide which had been exposed to air under various conditions were given.

Royal Astronomical Society, November 13.—Prof. H. H. Turner, F.R.S., president, in the chair.—Mr. P. H. **Cowell** read a paper on errors in the moon's tabular longitude as affecting the comparison of the Greenwich meridian observations from 1750 with theory.—The **Astronomer Royal** read a paper on the large sun-spots of October and November, and the associated magnetic disturbances, and exhibited photographs of the sun-spots taken at the Royal Observatory, and of the magnetic tracings, showing the most considerable disturbance to have been on October 31.—Mr. Newall showed and described a series of fine spectroheliographs of the great spot-groups, taken by Prof. G. E. **Hale.**—Mr. **Newbegin** showed photographs of the November sun-spots.—Spectroheliographs of the spot-groups taken on October 9 and 31 in K light by Mr. **Evershed,** showing the flocculent masses of faculæ surrounding the spots, were also thrown on the screen.—Dr. **Lockyer** considered the correspondence of magnetic storms with solar prominences was more marked than with sun-spots, and pointed out that magnetic disturbances become more decided as the prominences approach the poles.—Father **Sidgreaves** directed attention to the work at Stonyhurst, and to his conclusion that sun-spots are not the cause of magnetic disturbances, but that both phenomena have a common cause.—Father Sidgreaves then read a paper on a spectrographic study of β Lyræ at the Stonyhurst Observatory; he exhibited slides of a series of spectra taken at different dates, and explained his theory of the changes in the light of the star.—Prof. **Turner** gave an account of a method of photographing the moon with the surrounding stars, the results of which appeared very promising. In order to reduce its light the moon was covered by an opaque screen, in which was a slit; the screen was drawn slowly across the plate, and a sufficient exposure thus given, while images were obtained of stars down to about the ninth magnitude.—Many other papers were taken as read.

CAMBRIDGE.

Philosophical Society, November 9.—Mr. A. C. Seward, vice-president, in the chair.—Exhibition of living *Gongylus gongyloides,* a floral mantis, by Captain C. E. **Williams.** The insects exhibited show the pupal or nymph stage in the development of this mantis. They were hatched from the egg about January 18 of this year, and in the ordinary course should have attained the imago or winged state at the end of October. Development appears to have been arrested by the unsuitable climate of England, and by loss of appetite under confinement. The floral mimicry is effected by the foliaceous expansion of the prothorax around the insertion of the front pair of legs. This expansion is roughly diamond or oval shaped, and on the under side is of a bright azure blue tipped with rose purple at the angles and margins; in the centre of this disc is a deeply pigmented black spot of triangular shape. The front pair of legs are held closely folded together in the front of the coloured disc. The azure coloured disc resembles a small flower, and the black spot mimics the tube of a corolla. The attitude adopted by the insect when at rest and intent on catching its prey is an inverted position below a leaf or spray of leaves, the coloured side of the prothoracic disc being turned to the brightest light available. Insects, especially butterflies, are readily attracted by the floral simulation. The hinder part of the prothorax is drawn out into a long stalk and coloured a light green, enhancing the floral resemblance. The rest of the body is shaped and coloured to resemble a bunch of dead leaves, and is practically undiscernible amid its natural surroundings. The insects exhibited were brought from Rangoon.—Experiments in wheat breeding, by Mr. R. H. **Biffen** (see p. 92).

PARIS.

Academy of Sciences, November 16.—M. Albert Gaudry in the chair.—A new method of preparation of argon, by MM. H. **Moissan** and A. **Rigaut.** The argon is prepared in four stages, the first three of which, the removal of oxygen from the air by heated copper, concentration by passing over a mixture of lime and magnesium, twice, are identical with the processes worked out by Sir W. Ramsay and Lord Rayleigh. In the fourth stage the gas, after passing over a lime-magnesium mixture, is treated with pure metallic calcium at a dull red heat. Since calcium forms a hydride stable at 500° C., this removes at one operation the last traces of nitrogen and hydrogen. The apparatus produces one litre of pure argon in twelve hours.—Mr. G. W. Hill was elected a correspondant in the section of astronomy in the place of M. Schiaparelli, elected foreign associate.—On the analytical nature of the solutions of certain partial differential equations of the second order, by M. S. **Bernstein.**—On the use of the Schrader tacheograph in hydrographic work, by MM. F. **Schrader** and Ch. **Sauerwein.**—On the extraction of oxygen by the partial liquefaction of air, by M. Georges **Claude.** A method is described in which only a portion of the air is liquefied at a low pressure, and this liquid, with any preliminary evaporation, gives a gas containing 92 per cent. oxygen, the apparatus giving about 35 cubic metres of this per hour.—The measurement of very small angles of rotation, by M. Marcel **Brillouin.** Between the two Nicol prisms is introduced a thick plate of Iceland spar with parallel faces, cut at 45° to the axis, a half-wave plate, at 45° to the principal sections of the spar, and a second plate of spar similar to the first. It is possible to measure to

a half-second of arc with this arrangement.—On the determination of maxima and minima of transparency, by M. C. **Camichel.** A modification of the Gouy spectrophotometer, in which the two Nicols are replaced by a rotating disc, partly cut away in sectors.—Some remarks on the magnetic storm of October 31, by M. Em. **Marchand.** The author concludes that during magnetic storms the currents disturbing the earth's field are situated at least partially in the upper regions of the atmosphere. The magnetic storm coincided with the passage of an important group of sun-spots across the central meridian.—On a rigorous separation of the rare earths, by MM. G. **Urbain** and H. **Lacombe.** By the addition of the double nitrate of magnesium and bismuth to the mixture of double nitrates of rare earths, each earth has as its only impurity bismuth, which is readily removed, instead of another rare earth. The method has been applied with success to mixtures of samarium and gadolinum. On kermes mineral, by M. J. **Bougault.** On the acetylenic ketones, a new synthesis of the isoxazols, by MM. Ch. **Moureu** and M. **Brachin.** Ketones of the type of acetyl-phenyl-acetylene react quantitatively upon hydroxylamine, giving isoxazols.—On the retrogradation of starch, by M. L. **Maquenne.** The retrogradation is favoured by lowering the temperature and by the presence of minute amounts of mineral acids.—The influence of the nature of the external medium on the organic composition of the plant, by MM. Alex. **Hebert** and E. **Charabot.**—On the relation between the luminous intensity and energy of assimilation in plants belonging to different biological types, by M. Fr. **Weis.**—On the structure of the cotyledons and the disposition of certain adventitious roots in young labiate plants, by M. René **Viguer.**—On polymorphism in nitrates, by M. Fréd. **Wallerant.**—On some analogies of geological *facies* between the central zone of the eastern Alps and the internal zone of the western Alps, by M. Pierre **Fermier.**—On artesian wells, by M. D. **Pantanelli.** A consideration of the influence of the pressure exerted by the rock mass upon the subterranean sheet of water upon the well level.—On a new fossil-bearing level in the Keuper beds, by MM. M. **Piroutet** and Arm. **Laurent.** A comparison of the letters of the alphabet from the point of view of the speed of writing. The formation of a rational alphabet, by MM. André **Broca** and D. **Sulzer.** The present alphabet is badly conceived from a physiological point of view. A series of signs is suggested by means of which the speed of recognition of letters could be increased one-third.—The electrical resistance of the human body, by M. Stéphane **Leduc.** The electrical resistance of the human body is especially the resistance of the skin, and this, like all electrolytes, depends on the nature and concentration of the ions it contains.—Contribution to the treatment of cancer by the X-rays, by M. **Biraud.** The disease was a typical epithelioma, and had recurred after one operation. After four months' treatment with the X-rays the pain disappeared, and the size of the tumour was reduced three-quarters. Contribution to the study of hydrochloric acid in digestion, by MM. A. **Desgrez** and J. **Adler.**

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 26.

ROYAL SOCIETY, at 4.30.—Mathematical Contributions to the Theory of Evolution, XII., On a Generalised Theory of Alternative Inheritance, with Special Reference to Mendel's Laws: Prof. K. Pearson, F.R.S.—On the Distribution of Stress and Strain in the Cross-Section of a Beam: J. Morrow.—Some Experiments in Magnetism: T. C. Porter.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—The Testing of Electric Generators by Air Calorimetry: R. Threlfall, F.R.S.—The Edison Accumulator for Automobiles: W. Hibbert.

FRIDAY, NOVEMBER 27.

PHYSICAL SOCIETY, at 5.—An Electrical Thermostat: Horace Darwin.—On the Occurrence of Cavitation in Lubrication: S. Skinner.—A Lecture Experiment in Electrical Resonance: Dr. W. Watson.

ROYAL ASTRONOMICAL SOCIETY, at 8.—Lecture by the President, Prof. H. H. Turner.

MONDAY, NOVEMBER 30.

SOCIETY OF ARTS, at 8.—The Mining of Non-Metallic Minerals: Bennett H. Brough. (Cantor Lectures. II.)

INSTITUTE OF ACTUARIES, at 5.—On the Comparative Mortality among Assured Lives of Abstainers and Non-Abstainers from Alcoholic Beverages: Mackenzie Moore.

TUESDAY, DECEMBER 1.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Discussion of Paper on the Distribution of Mean and Extreme Annual Rainfall over the British Isles: Dr. H. R. Mill.

ZOOLOGICAL SOCIETY, at 8.30.—Note upon the Tongue and Windpipe of the American Vultures, with Remarks on the Inter-relations of the Genera Sarcorhamphus, Gypagus and Cathartes: F. E. Beddard, F.R.S.—On the Mammals of Cyprus: Miss Dorothy M. A. Bate.—On the Cause of Death of a Polar Bear recently Living in the Society's Gardens.—Dr. R. N. Salaman.

WEDNESDAY, DECEMBER 2.

ENTOMOLOGICAL SOCIETY, at 8.

SOCIETY OF ARTS, at 8.—The Fiscal Problem: Sir C. M. Kennedy, K.C.M.G.

GEOLOGICAL SOCIETY, at 8.—Note on the Garnet-bearing and Associated Rocks of the Borrowdale Volcanic Series: (The late) E. E. Walker—A Contribution to the Glacial Geology of Tasmania: Prof. J. W. Gregory, F.R.S.

SOCIETY OF PUBLIC ANALYSTS, at 8.—The Characteristics of some Almond and Allied Oils: Dr. J. Lewkowitsch.—Note on the Quantitative Estimation of Mechanical Wood Pulp in Papers: C. F. Cross and E. J. Bevan.—The Estimation of Aldehydes and Ketones in Essential Oils: H. E. Burgess. Note on the Estimation of Sperm Oil: L. M. Nash.

THURSDAY, DECEMBER 3

ROYAL SOCIETY, at 4.30.—*Probable Papers*:—On the Fructification of *Neuropteris heterophylla*, Brongniart: R. Kidston, F.R.S.—Histological Studies on Cerebral Localisation: Dr. A. W. Campbell.

LINNEAN SOCIETY, at 8.—On Littoral Polychæta from the Cape of Good Hope: Dr. Arthur Willey, F.R.S.—Notes on *Myriactis Areschougii* and *Coilodesme californica*: Miss May Rathbone.

RÖNTGEN SOCIETY, at 8.30.—A New Jointless Section Wound Induction Coil, and a Flat Spiral High Frequency Apparatus: Leslie Miller.

AËRONAUTICAL SOCIETY, at 8.—Report of the International Kite Competition—(1) Mathematical Portion: Prof. C. V. Boys, F.R.S.; (2) Descriptive Portion: Eric Stuart Bruce.—Preliminary Communication on the Longitudinal Stability of Aëroplane Machines: Prof. G. H. Bryan, F.R.S., and W. E. Williams.—The Balloon Ascents made by the late Mr. James Glaisher, F.R.S., for Scientific Purposes: W. Marriott.—The Mechanical Imitation of Bird Flight: W. Cochrane.

CHEMICAL SOCIETY, at 8.—On the Molecular Formulæ of some Fused Salts as Determined by their Molecular Surface Energy: J. F. Bottomley.—Acid Salts of Monobasic Acids: R. C. Farmer.—The Atmospheric Corrosion of Zinc: G. T. Moody.—The Solubilities of the Hydrates of Nickel Sulphate: B. D. Steele and F. M. G. Johnson.

FRIDAY, DECEMBER 4.

GEOLOGISTS' ASSOCIATION, at 8.—On Land, Freshwater and Estuarine Deposits, with Special Reference to Recent Excursions; Lecture by the President, Mr. H. W. Monckton.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Artificial Draught, as Applied by Fans to Steam Boilers: W. H. A. Robertson.

CONTENTS.

THURSDAY, DECEMBER 3, 1903.

THE REFORMATION OF THE TEACHING OF GEOMETRY.

Elementary Geometry, Practical and Theoretical. By C. Godfrey, M.A., Winchester College, and A. W. Siddons, M.A., Harrow. Pp. xi+355. (Cambridge: University Press, 1903.) Price 3*s.* 6*d.*

A New Geometry for Schools. By S. Barnard, M.A., Rugby, and J. M. Child, B.A., Technical College, Derby. Pp. xxvi+514. (London: Macmillan and Co., Ltd., 1903.) Price 4*s.* 6*d.*

EIGHT years ago the writer of this review, when publishing a small book on geometry for the use of pupils of eight or nine years of age, was assured by many friends that the attempt to get rid of Euclid's order and language was a hopeless one, and that, even if it were successful, the foundations of all logical thought in England would be destroyed. Against a strong conservatism it seemed vain to point out that the great developments of modern geometry were made by European mathematicians who were not brought up on Euclid. The question had been tackled before, but with no success. When, however, the British Association and the Mathematical Association appointed committees to grapple with the matter in earnest, the victory of reform was assured. The former body thought it wise to lay down generalities, while the latter went into such minute details as to the course to be pursued by teachers, and the propositions which should be included in school instruction, that it has been possible to embody its recommendations in definite systematic treatises, such as the two excellent works the titles of which are quoted above.

That some recognised order of deduction must be established is a fact which is forced upon anyone who has to perform the part of an examiner, more especially for the public service, and the fact that there is a close agreement, not only in method, but in order, between the two works before us shows that the difficulty of dethroning Euclid is quite imaginary.

Each of these books is a vigorous protest against the extraordinary contention which we have sometimes heard, that "you must make bad figures in geometry so that the logical faculty of the pupil shall receive no assistance from them." Rule, compass, set square, and protractor are now the tools with which the young pupil begins his acquaintance with this subject; and we venture to say that, under the new system, the typical schoolboy will change his attitude of repugnance to "that beastly Euclid"; the subject will actually become popular.

The work of Messrs. Godfrey and Siddons begins with fifty-nine pages of "experimental geometry," in which the pupil is taught to draw various figures by the use of scales, compasses, &c. There is no formal list of *definitions*; the definitions are given as they are required.

Messrs. Barnard and Child open with a list of definitions, each of which, however, is illustrated by a good clear figure, and then follows part ii. of the book, which is "practical," and occupies 224 pages. This is occupied wholly by constructions, and many of these constructions are to be taken in conjunction with corresponding theorems, to which the pupil is duly referred in part iii. of the book, which is "theoretical." It must not be supposed, however, that part ii. is merely constructive—that is, that the pupil is directed to perform certain operations without understanding the reason. The constructions are, almost invariably, accompanied by a justifying proof, and the whole collection seems to be exhaustive. Here the nature of an *envelope* is also explained, and a few examples of the drawing of envelopes are given.

Under the head of constructions we find also the definitions of the trigonometrical functions, and some constructions founded thereon, so far as one angle is concerned. There is also a section dealing with the displacement of a lamina in its own plane, and the nature of the instantaneous centre of rotation. It is needless to say that the plotting of figures on squared paper and the measurement of areas thereby occupy a fair space in this section. The principles of folding and superposition, also, are largely employed as a means of proof. There is no doubt that in this work of Messrs. Barnard and Child the teacher will find every requisite for the modern teaching of geometry, including a very large number of illustrative examples. The collection of all construction propositions into one large section by themselves is the main difference between the two works before us.

In the work of Messrs. Godfrey and Siddons the constructions appropriate to each branch of the subject form a special section in that branch; thus constructions relating solely to triangles are taken together in the part of the book dealing with congruent triangles, those relating to circles in the part dealing with circles.

There is a remarkable similarity of procedure in the theoretical or deductive portions of both works. Each begins with the discussion of angles at a point, then follow the treatment of parallel lines, angles of a triangle and external angles of a polygon, congruent triangles, inequalities (*i.e.* of sides and angles of a triangle) and parallelograms, closely followed in each work by the discussion of areas.

Messrs. Godfrey and Siddons adopt the invariable plan of accompanying each proposition with a large series of examples and applications. Sometimes we come across a well chosen practical example calculated to enlist the interest and sympathy of the young pupil—such as the application of a simple case of congruent triangles to the finding of the breadth of a river, of which a figure is given. The work is a charming one, marked by great simplicity.

Squared paper and the plotting of coordinates find also ample space in this book. Geometry is supposed to have arisen from the necessities of land-surveyors, but any such mundane connection has been so long severed that we find ourselves astonished when we actually see (p. 180) an irregular figure plotted and its area estimated by a process of give and take—and this in the midst of some of Euclid's propositions, too! Truly the times have altered rapidly—a still further

proof of which fact is furnished by the liberty which each of these excellent works takes with Euclid's Prop. 19, Bk. vi.—"similar triangles are to one another in the duplicate ratio of their homologous sides"—mysterious but high-sounding to countless generations of schoolboys. Here it is, in identical words in both books, "the ratio of the areas of similar triangles, or of two similar polygons, is equal to the ratio of the squares on corresponding sides," brought down to definiteness and intelligibility at last!

There are certain time-honoured propositions in the treatment of which teachers will take a special interest, and none more prominent than Euclid's Prop. 1 of Bk. vi. Messrs. Barnard and Child prove it by assuming that the bases of the triangles are multiples of some common length, while Messrs. Godfrey and Siddons (p. 175) treat it as a mere result of the fact that the area of a triangle is half the product of a base and the corresponding perpendicular—both proofs, of course, resting on the same ultimate assumption. In justification of such proofs it may be said that no useful purpose will be effected by an early discussion of incommensurable quantities.

There are many things—such, for example, as the constancy of the product of the radii vectores from a fixed point to a circle, the nature of a tangent as a limiting position of a chord, &c.—in which we have an agreeable and useful variety of treatment in these two works, but the limitation of space renders further reference to them here impossible.

G. M. MINCHIN.

"SEMI-DARWINIAN" SPECULATIONS.

Doubts about Darwinism. By a Semi-Darwinian. Pp. vi+115. (London: Longmans, Green and Co., 1903.) Price 3*s.* 6*d.*

THE preface of this work informs us that its author has endeavoured to conform strictly to the principle laid down by Lord Kelvin, as follows:—"If a probable solution, consistent with the ordinary course of nature, can be found, we must not invoke an abnormal act of Creative Power." Unfortunately the "Semi-Darwinian's" practice is not in accord with his profession. Whenever he meets with a problem in evolution which appears to him inexplicable on the lines of natural selection, so far from seeking for "a probable solution, consistent with the ordinary course of nature," he resorts at once to the intervention, by a direct creative act, of "a Being possessing intelligence, intention and power." This is bad science, and we much doubt whether it is good theology.

Opinions have differed, and will doubtless for a long time continue to differ, as to the extent of the influence of natural selection as a factor in evolution. Darwin himself, as is well known, thought that its operation might be supplemented by that of the factors adduced by Buffon and Lamarck. Whether in view of the increase of knowledge since Darwin's day, and of the numerous cases of difficulty which have lately been satisfactorily explained on the basis of natural selection, he would have been led to discard those hypotheses that involve the hereditary transmission of acquired characters, it is, of course, impossible to say. But it certainly seems probable to those workers in whom the Darwinian tradition is strongest that their leader, were he living now, would attribute more rather than less importance to his distinctive principle of natural selection. However this may be, the fact remains that if by "Darwinism" be meant the natural selection of "accidental" variations, the doubt as to its claim to be the sole factor in evolution is a doubt that was felt by Darwin himself. Hence we demur to the title of the present work.

A matter of greater importance is the author's attempted demonstration of the impossibility of explaining certain phenomena on Darwinian principles. It is true that some of the facts he adduces have been felt as difficulties, but not, as a rule, in the way that he supposes. To answer his objections point by point would be lost labour, for he shows on almost every page that he is unacquainted with the conditions of the problem. His remarks on the subject of vision, of reproduction, of embryology, to take a few instances, are those of a disputant who has entered the lists without the necessary equipment. Argument with such an opponent is unprofitable. As an example of the failure of the "Semi-Darwinian" to master the present-day aspects of the subject, we may take his treatment of the caterpillar and beetle-stabbing instincts of Sphex and some other genera of fossorial Hymenoptera. He quotes Romanes's expression of a desire for further investigation of the facts, but appears to be quite unaware that the need has been to a great extent supplied by the labours of two industrious and accurate naturalists in America, who have put an entirely new complexion on the case as it was known to Darwin. We have no wish to detract from the merits of so zealous and patient an observer as Fabre, to whose writings those who have discussed the habits of Sphex, Ammophila, and their allies have generally been indebted for their facts; but it is impossible to study the recent work on the subject without recognising that Fabre's inferences are sometimes unwarranted. Even before the new facts had been brought forward by G. and E. Peckham, the difficulties of explanation on the lines of natural selection, though great, did not seem insuperable; they may now be said to have disappeared.

But it is not only on such points of detail as the foregoing that the author shows his absence of qualification for dealing with the modern phases of the evolutionary problem. To say nothing of other omissions, the whole series of considerations specially associated with the names of Baldwin, Lloyd Morgan and Osborn is entirely ignored by him, nor does he give any sign of being acquainted with recent views on the subject of heredity. In short, as an attack on the adequacy of natural selection, his book, besides being ineffective, is hopelessly belated.

Supposing, however, that the author's strictures were well founded; that he had really contrived to point out certain stages in the evolutionary process which are not, and apparently never can be, explained on the basis of natural selection—what then? Surely in accordance with his own canon his next step should be to search for some other natural cause of the

phenomena that baffle him. To fly at once to the hypothesis of direct "intervention" by a "higher intelligence" is as much as to say that a science of life is impossible. It is not our province to enter into the theological aspects of the matter; we would only remark that the author's language on this head appears to us to be a curious instance of survival from a bygone epoch. When, as in the eighteenth century, deistic conceptions o nature were rife, the idea of "interference" or "intervention" rose easily enough in the minds of devout persons. The only alternative seemed to be the complete banishment of the Deity from his universe. But in so far as deism is discredited by evolution, its correlative notion of "interference" must share in that discredit; and it is, to say the least of it, somewhat surprising to find the idea revived in the supposed interests of religion by one who, like the "Semi-Darwinian," professes neither to "question the general doctrine of evolution" nor to "desire to disturb the position of the 'Origin of Species' as an epoch-making book." F. A. D.

WATER SUPPLY.

Water Supply. A Student's Handbook on the Conditions Governing the Selection of Sources and the Distribution of Water. By Reginald E. Middleton. Pp. ix+168. (London: Charles Griffin and Co., Ltd., 1903.) Price 8s. 6d. net.

THE provision of a pure and ample water supply is constantly growing in importance with the development of sanitary science and the rapid increase of the population in cities and large towns; whilst adequate and unpolluted sources of supply have to be sought at greater distances away, and in a country of limited area, such as England, will before very long become difficult to obtain, yielding sufficient quantities of water to meet the growing requirements of the inhabitants. Accordingly, water supply has within recent years become one of the most universally needed branches of engineering; whereas increasing difficulties are encountered in the execution of the requisite works. The enhanced value and interest thereby conferred on works providing supplies of water, have naturally led to the publication of several books on the subject in the last few years; but the present book differs from its more elaborate and comprehensive predecessors, in dealing with principles rather than with practice, and in being intended as a sort of introduction to those larger books, and for engineering students rather than for engineers.

The first introductory chapter gives a rapid sketch, within the limits of six pages, of the various points which have to be taken into consideration in devising a scheme of water supply, from the selection of a source to the delivery of the water to the consumer; and it provides a clear and useful summary of the questions which form the subjects of the succeeding chapters. The second and third chapters deal respectively with the requirements as to the quality and the quantity of water, the former describing the mineral and organic impurities liable to be found in water, the sources rom which they are derived, and their relative importance; whilst the latter explains the variation in the daily consumption per head of population in different localities, under different conditions, at different seasons, and according to the amount of waste, also the provision necessary for increase in population, the method of measuring rainfall, the gauging of the discharge of streams and rivers, and the estimation of the available yield from the different sources of supply.

In the following chapter, on storage reservoirs, the form and construction of earthen dams, and the various arrangements resorted to for regulating the discharge of the water from the outlet of reservoirs, are the main subjects dealt with; and under the heading "Compensation Water," concluding the chapter, after explaining this important requirement, a description is somewhat irrelevantly added of the earthen embankments of the Staines reservoirs, with which the author is professionally connected, the only definite reference to an executed work given in the book. The next chapter is devoted to the calculations of stability of masonry dams by analytical methods, but a graphical treatment of the statical problems involved would be found both clearer and simpler. An interesting description is given in chapter vi. of the purification of water by the ordinary English system of slow filtration through sand; and a brief reference is made at the end of the chapter to the American system of rapid filtration by aid of a coagulant, usually aluminium sulphate, introduced into the water.

The construction of service reservoirs for providing against fluctuations in the consumption is considered in a short chapter; and it is followed by a fairly complete investigation of the flow of water through pipes, occupying twenty-seven pages. The last three of the eleven chapters in the book, relating to distribution systems, pumping machinery, and requirements in connection with waterworks, together covering less than nine pages, add more to the number of chapters and the apparent scope of the book than to actual information about waterworks, the last chapter, more particularly, consisting simply of an appeal for the collection of additional and more detailed statistics in regard to rainfall, evaporation, the discharge of rivers and streams, and other matters pertaining to water supply. The book is illustrated by four folding plates and sixty-six figures in the text, and a short index is added at the end.

Though some subjects, such as aqueducts from impounding reservoirs, water meters, and sections of typical masonry dams are not described, and the information about springs and wells is scanty, and the book, therefore, does not provide a complete account of waterworks, it gives a considerable amount of practical information, combined with valuable suggestions for the guidance of waterworks' engineers in several of the chapters. The way, however, in which the book is written renders it more likely to be used for reference than for reading straight through; and, moreover, the number of short paragraphs into which it is broken up, even when treating of a single subject, is calculated to distract the reader. Nevertheless, the engineering student will find a considerable store of useful information and valuable hints dispersed

throughout the book; and it should serve as a convenient guide for leading on students to the intelligent study of more complete and elaborate treatises on water supply.

THE MATHEMATICAL THEORY OF CRYSTAL STRUCTURE.

Mathematical Crystallography and the Theory of Groups of Movements. By Harold Hilton, M.A. Pp. xii+262; with 188 figures in the text. (Oxford: Clarendon Press, 1903.) Price 14s. net.

UNDER the fostering care of the energetic professor a small but vigorous school of mineralogy is growing up at Oxford. We are not surprised to note in the preface that it was due to Prof. Miers's suggestion that Mr. Hilton undertook the task which he has so successfully accomplished. Mr. Hilton has had a distinguished career at Oxford, and it is with pleasure we observe that a mathematician of his attainments has turned his attention to a subject which receives such scanty consideration in this country.

Mr. Hilton's book appears at an opportune moment, since it is the generally accepted idea that the geometrical theory of crystal structure has reached something like finality. A good historical account of the development of the subject is contained in the British Association Report, 1901, and the present work supplements that survey by supplying the detailed reasoning. The scope of the book is more restricted than the rather wide title would lead a reader to suppose, and it is almost wholly concerned with the symmetry and structure of crystals. With the exception of a few chapters, it follows closely Schönflies's "Krystallsysteme und Krystallstructur," but some features are introduced from the writings of Jordan, Fedorow and Barlow. Very slight allusion is made to Sohncke's work. We think it would have added to the value of the book had a page or two been devoted to his systems. Of course, they appear among the space-groups; but at the same time some Sohncke-system forms the basis of every space-group. This is Barlow's way of considering the subject, and may be found easier of comprehension by many readers, especially if the theory of groups be new to them. The book is distinguished by the fine series of diagrams of the space-groups, which have been drawn independently in the way suggested by Fedorow. The explanation of the figures, which is given on p. 171, might have been made more conspicuous so as to catch the eye more readily. The absence of such diagrams appreciably adds to the difficulty of understanding Schönflies's work.

Mr. Hilton divides his book into two parts. In the first he determines the thirty-two classes of centrosymmetry, which obey the law of rational indices and are therefore alone applicable to crystals. Another, and perhaps more logical method, is to assume that crystalline structure is cross-grained; that is to say, that a lower limit can be found to the distances between the elementary parts, whatever they may be. With this assumption, it may be shown that the only possible axes of symmetry have respectively 2-, 3-, 4- and 6-fold symmetry. The law of rational indices alone is not entirely satisfactory on account of a peculiar case of pseudotrigonal symmetry which in that way arises. This part includes an elaborate chapter on the coordinates of equivalent points, and a chapter of considerable interest on the growth of crystals.

The second part corresponds very closely to the second part of Schönflies's book. After determining the fourteen varieties of lattices, the author discusses the properties of geometrical operations and the infinite groups of movements. The dynamical flavour which unavoidably clings to the subject is unfortunate, and without a note of warning the reader may be misled into the idea that something in the nature of a movement does actually occur. On p. 159 the author proves the fundamental proposition connecting the space-groups with the corresponding point- and translation-groups, and in the succeeding six chapters he deduces the 230 space-groups belonging to the six systems. A chapter follows on the partitioning of space, with special reference to Schönflies's elementary cell.

In the next chapter, on crystal-molecules, mention is made of attempts that have been made to assign arrangements to particular substances. It may be noted that at the present day there is a tendency to regard the molecules which compose a crystal, or rather their spheres of influence, as being in contact. In that case Barlow's theory of closest-packing would have some justification. A brief historical sketch brings the book to a close.

Mr. Hilton has prepared a masterly exposition of a difficult subject, and we can heartily commend the book to the attention of crystallographers.

OUR BOOK SHELF.

Das Haar, die Haarkrankheiten, ihre Behandlung und die Haarpflege. By Dr. J. Pohl. Fifth revised and enlarged edition. Pp. 178. (Stuttgart: Deutsch Verlags Anst., 1902.)

THIS is a popular treatise upon a subject which has received too little attention from scientific observers. The first part of the work deals with the structure and development of the human hair, with a brief account of the methods of investigation. The author, with the painstaking thoroughness of the German savant, has made a large number of researches into the rate of growth and the normal fall of the hair. The common belief that cutting the hair promotes its growth is shown to be erroneous. Each hair has, on the average, a normal life of about seven years, at the end of which time it falls out and is replaced by a new one. In health there is a normal fall of hair which varies somewhat with the age of the individual.

The second part of the work is devoted to the diseases of the hair and their treatment, and to the care of the hair. The author considers that in most cases oil or pomade is beneficial, but he insists that the quantity applied must be small. The vexed question of washing the hair is discussed. In individuals in whom the scalp is healthy, Dr. Pohl is of opinion that too frequent washing is inadvisable. He advocates the use of bran, yolk of egg, and other demulcents in the water used. Rapid and thorough drying of the hair after washing is insisted upon, especially for ladies.

As an important cause of baldness in men, the author places the wearing of stiff and heavy hats, which for hours together compress the blood-vessels of the scalp and impair its nutrition and that of the hair. He points out that the common straw hat is often responsible for as much compression as the cylinder hat.

The part played by general organic and nervous diseases in causing baldness and premature greyness is considered, and these conditions obviously demand treatment at the hands of the physician. The *rôle* of micro-organisms in the production of baldness is perhaps insufficiently dealt with in the light of the work of Sabouraud and others in seborrhœa. Attention is, however, directed to the effects of the parasites of ringworm and favus. But in these diseases and in alopecia areata the patient will naturally seek medical advice.

Though the work is obviously written as a popular treatise, its perusal will be of value to the medical practitioner, who very rarely gives attention to the subject, which is one of great interest to the public, who are only too ready to fly to various nostrums brought to their attention by assiduous advertisement.

Radiant Energy. A Working Power in the Mechanism of the Universe. By R. W. O. Kestel. (Port Adelaide, 1898.)

The loose and unscientific use of terms, such as force, the curious absence of ordinary mechanical conceptions, as, for example, inertia, and the almost puerile objections raised against the Newtonian theory of planetary motion, sufficiently proclaim this book to be the work of the untrained amateur with original ideas. In consequence, none but a discerning reader will profit by its perusal. Yet the closing sentence—"Radiant Energy is a Working Power in the Mechanism of the Universe"—is a remarkable one, considering that the book is dated as having been published five years ago. The researches of Nichols and Hull in America, and Lebedew in Russia, on the pressure due to radiation have established the author's contention. In the chapter on comets some of our present notions of the cause of comets' tails are clearly anticipated, but in applying the same idea to other parts of the mechanism of the universe, the author has fallen into the error of imagining a repulsion from the sun "just thirty thousand million times too large." The main idea is that "a repelling force radiating from the sun" "partakes of the sun's motion of rotation," and "is carried round in the direction the sun is revolving." The author justifies himself by mechanical analogies, and uses the idea to account for the origin of both the orbital and axial motions of the planets. By the aid of a model in which the repulsive force is represented by a stream of horizontal water jets emanating from a rotating nozzle, many of the phenomena of planetary motion, it is claimed, can be demonstrated experimentally. The idea, although so crudely expressed, when applied to our present knowledge does seem to possess a real value. Light, radiating from the sun, should, it seems, be affected by the rotation of the sun, in such a way that the resultant of the pressures from all parts of the solar surface which reach a planet passes through a point displaced from the centre in the direction of the edge approaching the planet. The same would apply to pressure exerted by normally projected corpuscles or electrons. The effect is to produce a positive acceleration of the planet in its orbit. Whether there is also a couple acting to produce rotation suggests a nice problem for the astronomer. Is it possible that these infinitesimal pressures acting over infinite time could originate the motions of the planets? Could these pressures maintain the planet in uniform motion through a resisting ether? These problems should now admit of a definite answer, and seem worthy of a more competent analysis than the reviewer is able to give.

F. S.

Physikalisch-chemische Theorien. Von A. Reychler, nach der dritten Auflage des Originals bearbeitet von B. Kühn. Pp. xii+380. (Braunschweig: Vieweg und Sohn, 1903.) Price 9 marks.

For its compass this volume contains a wonderful amount of well-arranged material. It covers the ground usual in elementary works on physical chemistry, but by concise treatment of descriptive and theoretical matter the author finds room for much detail that has no place in other books of equal size. This gives it considerable value as an elementary work of reference, whilst it rather detracts from its suitability to the needs of the beginner.

What will probably render the book most interesting to English readers is the substitution by the author of a peculiar hypothesis of hydrolytic dissociation for Arrhenius's hypothesis of electrolytic dissociation, which, however, is duly expounded in its place. The author conceives that when a salt is dissolved in water it dissociates into the corresponding acid and base, the degree of dissociation being presumably equal to that attributed to the salt by Arrhenius's theory. The behaviour of acids and bases themselves is explained by an auxiliary hypothesis which postulates the separation from the total solvent water of a special kind of water molecule which cannot pass an osmotic membrane permeable to the other water molecules. Unfortunately the author makes no attempt to carry out his theory in detail, and so the reader is left in a somewhat dubious state of mind regarding its merits.

The author reproduces on p. 78 Traube's erroneous deduction of the degree of association of a liquid from the results of the volume method. A glance at the formula shows that it is only correct when $x=1$ or $x=2$, and is erroneous for all intermediate values.

Electrical Engineering Measuring Instruments. By G. D. Aspinall Parr. Pp. viii+328. (London: Blackie and Son, Ltd., 1903.) Price 9s. net.

Mr. Aspinall Parr has aimed at giving a description of all the leading electrical measuring instruments on the market, and he has carried out this object with a painstaking thoroughness worthy of a better cause. There can be few instruments enjoying any respectable sale which are not included in this book, and the descriptions are exceedingly clear; so also are the illustrations of the working parts, yet the reader gains little more from the book than he could gain, with perhaps a trifle more trouble, from a perusal of the makers' catalogues. "Fig. 70," to quote from the book, "shows the general appearance of this instrument with the index pointer set to 102 and the pointer clamped at zero," and Fig. 70—a picture of a brass case and a paper scale—is typical of quite 50 per cent. of the 370 excellently reproduced illustrations. The importance of instruments to electrical engineers is not to be underrated, and it is quite true, as the author says in his preface, that the literature of the subject has been neglected. But the literature that is needed is not a collation of catalogues, but something that may guide the purchaser in selecting an instrument suited to his purpose. Mr. Parr makes a point of having avoided comparison, yet this is the very thing that is wanted; in many cases one can form no idea whether the instrument is suited for high or low voltages, for large or small currents, what is its accuracy under different conditions, or what even is the general accuracy obtainable with instruments of a

given type. There is a general discussion of the theory of each class of instrument, but this is of too fragmentary a nature to be of value; we may direct attention to the fact that the discussion of hot-wire instruments is incorrect; no mention is made of the cooling of the wire, and it is apparently assumed that the instrument is kept in the circuit for exactly one second whenever a measurement is made.

It is a pity, seeing how much trouble has been taken with the drawings of the working parts and the wide acquaintance with instruments which is evidenced, that Mr. Parr has not given us a more valuable work. As it is, the book may prove useful to those who may be called upon at any time to put something right in an instrument which has broken down. M. S.

Life in Mind and Conduct: Studies of Organic in Human Nature. By Henry Maudsley, M.D. Pp. xv+444. (London: Macmillan and Co., Ltd., 1902.) Price 10*s*. 6*d*. net.

Readers of Dr. Maudsley's former volumes will find in the present work both the faults and the merits of its predecessors. Dr. Maudsley here, as always, writes with a great deal of epigrammatic felicity, and shows from time to time vivid flashes of insight into human character; here, too, as formerly, he often mars the effect of his epigrams by a tendency to re-elaborate them into rhetorical "common-places," in the technical sense of the term. The fundamental positions of the book may be reduced to three: the worlds of mind and of matter in reality form a single continuous evolution; "whatever is, is right," being an inevitable result of the laws of that evolution; "private vices" are, as Mandeville taught, "public benefits," inasmuch as vice and virtue are alike expressions of the needs of the "social organism." On this last topic Dr. Maudsley writes a great deal that is striking and not a little that is true, but he never explains how upon his principles the recognition of *any* distinction between right and wrong can be other than an absurdity. If the whole of morality is devotion to the advancement of society, and if, again, the advancement of society is *equally* promoted by virtue and by crime (and this is what Dr. Maudsley more than once asserts), why should we make any distinction between the hero and the criminal? That God brings good out of evil is a truism; it does not follow that the evil is therefore as good as the good. A. E. T.

Elementary Bacteriology. By M. L. Dhingra, M.D., C.M., Edin., D.P.H., Camb. Pp. xiv + 145. (London: Longmans, Green and Co., 1903.) Price 3*s*. net.

From the preface we learn that this little book has been written especially for Indian students and practitioners. Too much has been attempted in the space, and the descriptions suffer from extreme brevity, only the fringe of the various subjects dealt with being reached. For example, no less than sixteen disease conditions are discussed in about forty pages, excluding the space allotted to illustrations, &c. The information given, so far as it goes, is as a rule accurate, the introductory portion upon the morphology and general biology of the bacteria being perhaps the most satisfactory. Subjects of especial interest to the Indian practitioner, *e.g.* protective inoculation against cholera, receive little more attention than many others which only indirectly concern him; actinomycosis is allotted more than a page, madura disease less than half a page. In the concluding portions of the book immunity, the principles of bacteriological technique, and antivenene are similarly dealt with. The book is well and sufficiently illustrated. R. T. Hewlett.

LETTERS TO THE EDITOR.

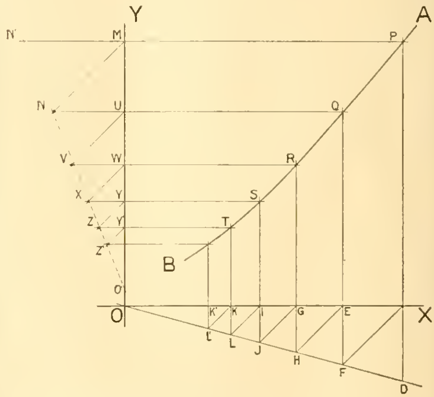
[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

A Useful Empirical Formula.

My note in Nature of October 8 may be extended. I found that one of my pupils, Mr. Glasgow, was assuming that the expansion and compression parts of a gas engine diagram followed laws of the type pv^n constant; in cases where there was a probability that the clearance had not been measured accurately, so that v being the measured volume and c the constant error, he assumed $p(v+c)^n$ to be constant, and he was enabled to find c from the curve. There is no reason to believe that these curves ought to have such a law, although, curiously enough, following this assumption, the clearance obtained from the compression curve is usually not very different from that obtained from the expansion curve. Mr. Glasgow's method of finding c is much the same as what I shall now describe. An empirical formula of the type

$$y = a + bx^n$$

would be exceedingly useful in many parts of pure and applied science if, when given a table of values of y and x, we could readily find a, b and n. I have often sought for a method of working, but without success. If a is zero, we have only to plot log y and log x as the coordinates of points on squared paper. If a is not zero, there is a clumsy method of using logarithmic paper which may be adopted,



but it is not satisfactory. We now have a method easy of application. Thus values of x and y being given, draw the curve AB shown in the figure. Set off any convenient angle DOX. Select the point P. Draw PD, XF, FEQ, EH, &c., the lines XF, EH, &c., being at 45°. Project horizontally from the points PQR, &c., to M, U or N, W or V, &c., letting lines at 45° from M, U, &c., meet the horizontals at N, V, X, &c. If the above law holds, N, V, X, Z lie in a straight line. If they lie only approximately in a straight line, draw the line N′O′ lying most evenly among them. Then OO′ is the value of a, and n is

$$\log(1 + \tan N'O'Y)/\log(1 + \tan DOX),$$

and b is readily found.

I may say that we have no great difficulty in testing whether a curve follows approximately a law like

$$y - \alpha = b(x - \beta)^n.$$

For this we have the curve on *tracing* paper, and we try as in the figure, then slide the curve a short distance in the direction x and try again, and so on. After a little study Mr. Glasgow has discovered a number of interesting properties of curves of these types. John Perry.

A Simple Lecture Experiment with Radium Rays.

WHILST preparing some experiments for a lecture on this matter, I found a very simple device to demonstrate the important fact that radium rays are very easily transmitted through a high vacuum; and I am not aware that it has been published before in this way. I had at my disposal the strongly acting compound of radium bromide which is prepared at Brunswick, in Germany; 10 mgr. were enclosed in a small box of ebonite with a mica cover having a diameter of 20 mm. This was put down in a Dewar's tube with vacuum jacket, as is commonly used in experiments with liquid air, and held in place by a stopper of cotton wool. The tube was then turned upside down in a little dish with some mercury, so as to obtain a perfectly enclosed space, and the radium rays could only get out by the vacuum walls or through a thick layer of mercury; by taking enough of this dense liquid the escape may be stopped altogether. Putting now a charged sensitive gold leaf electroscope at a distance of 5 cm. from the tube, a leakage instantly sets in, so as to cause the instrument to be wholly discharged in fifteen seconds. I also tried a vacuum jacketed tube with silvered walls, but though this affords much better protection against the heat rays, I did not detect any considerable difference with regard to the former experiment; the discharge was almost as quick, demonstrating that radium rays are not reflected to an appreciable amount. Even when the radium bromide was put into a large Dewar's silvered balloon of 5 litres capacity, wrapped in cotton wool, and enclosed in a wooden case, in which liquid air would be preserved during more than a fortnight, the charged electroscope came to zero in half a minute when it was placed very near to it. The experiments are effective and easily arranged.

L. BLEEKRODE.

The Hague, November 20.

Nuclei and Ions

IT is perhaps ungracious to reply to a review. I appreciate very fully that in cases of papers like mine, which take an isolated position and are written by a man who is not infallible, the task of the reviewer is burdensome enough. But Mr. C. T. R. Wilson's summary of several years of my work (October 8, p. 548) seems to me unnecessarily captious, and I am obliged to answer in self-defence.

I will not quarrel with Mr. Wilson about the titles of my papers, or about references to my first paper ("Experiments with Ionised Air"). I have had occasion to come back to it myself since (*Amer. Jour. Sci.*, xv., 105; *ibid.*, 217), and shall presumably do so again.

Turning to the second paper ("Structure of the Nucleus"), the impression given is that my first chapter is superfluous. The particular direction in which Mr. Wilson thinks it superfluous, *i.e.* the determination of reciprocal relations in the number of ions and nuclei arising in any process, I consider of special importance, as I shall explain below. Apart from this, the gist of the chapter is the (to me) very interesting result that phosphorus as a nucleator suddenly bursts forth into maximum activity at about 13°. The smoke at higher temperatures is a degradation. If I had made these experiments earlier I should not have drawn the comparison between the number of nuclei and the number of ions which Mr. Wilson impales. Recently (*Amer. Jour. Sci.*, xv., 217) I have departed widely from this early result.

With regard to my work on coronas, I had hoped that any rational attempt at systematisation would at least be tolerated. It was something, I thought, to plough through so bewildering a display and to get the general lay of the land in that deceptive colour territory, to distinguish sharply between the axial and the coronal colours, to ascertain that even in the former case the particles are large in comparison with the wave-length of light. So far as I know a discrimination of the evidence obtainable from the steam jet and the condensation chamber has thus for the first time been given. Mr. Wilson, however, has no encouragement. He gravely doubts "whether the method can be made a trustworthy one." Unfortunately I did not know this, for I have since ventured to repeat the whole work (*Amer. Jour. Sci.*, xvi., 325, and a forthcoming paper in Boltzmann's "Jubelband"), with corrections of method and calculations, obtaining suggestive periodic variations of the coronal apertures for a given colour and the sizes of the cloud particles. I have recently succeeded in catching, holding, and approximately measuring under the microscope the particles of the finest fog (beyond the largest green-blue-purple corona). Again, in a year's continuous observation by my coronal method of the atmospheric nucleation of Providence (lest this lead to "misconception," let me say that no theological bearing is implied), I have found the data useful (*Physical Review*, xvi., 193; xvii., 233).

My interpretation of the experiments on the diffusion of the nucleus is in error, but I have long since corrected it (fully in *Amer. Jour. Sci.*, June, p. 472, briefly in *Drude's Annalen*, August, p. 1144). Hence I do not find Mr. Wilson's belated comments particularly helpful. I was so fully convinced that the excessively slow diffusions observed could only be due to the motion of nuclei that I failed to see that the small coefficients of the hydrocarbon vapours would be virtually accentuated in large degree by the occurrence of diffusion from saturated to somewhat less saturated vapour. But this bad break is not of primary significance in its bearing on my work; the original purpose of these experiments with hydrocarbon vapours, which Mr. Wilson overlooks, was this:—If the ionisation accompanying nucleation is favourable to condensation, it should be particularly so, presumably, in the case of the vapour of an ionising solvent like water. Hence if non-ionising solvents like the hydrocarbons be substituted for water, the absence of effects attributable to ionisation might be discernible. No essential difference was detected.

In the following remarks relative to nuclei produced by shaking liquids, it is astonishing to find a faint note of approval, but Mr. Wilson does not intend that it shall be taken too seriously. "There is nothing new," he hastens to add, "that nuclei of this kind exist." Verbally, this may be true, but the implication of the whole paragraph is much broader. He does not point out, however, where I may find a prior succinct statement, identical with the view which I give for the persistence of the solutional nucleus.

My "extraordinary hypothesis," as Mr. Wilson calls it, is a critical alternative, put forward to ascertain whether it has been proved that ionisation has an immediate effect on condensation, or whether such condensation is not even now to be regarded as a mere question of the size of the nuclei. The hypothesis should, in the first place, be fairly stated. In any region of intense ionisation there must be a correspondingly marked tendency to synthesis. The nucleus is the stable result of this synthesis. What its structure is to be depends, therefore, primarily on the chemical ingredients of the medium out of which the nucleus is made. Given a definite medium, simple or complex, and one may anticipate a nucleus of definite size and a corresponding supersaturation needed for condensation. My contention is, then, that if nuclei are formed by the X-rays at the anode and the kathode, they are liable to be different, because the ingredients out of which the nuclei are to be compounded are different. If they do not vary in size but merely in number with the intensity of the radiation, this need be no more surprising than that the products of combustion remain the same within a wide range of temperature.

My reasons for this view may best be developed in connection with the case of phosphorus. Mr. Wilson dismisses it by stating, "The answer is simply that the nuclei causing the phosphorus clouds are not free ions like those produced by the X-rays." Let me explain why I fail to grasp the term "free ion." The phosphorus nucleus, as experiment shows, is always a relatively persistent body, while the initial ionisation is to an equal degree characteristically fleeting. Usually before the emanation has been made available for condensation, only a few per cent. of the initial ionisation is left. Meanwhile, the nucleation or condensational activity has suffered no commensurate decline (*Physical Review*, xvi., 288). It is probable that the whole series of condensations subsequently to be evoked follow in the absence of ionisation.

The case of water nuclei is in this respect almost the same, except that the initial ionisation (I shall venture to call it so, since it discharges both positive and negative

electrification; *cf. Amer. Jour. Sci.*, xv., 105) is rarely neutral as a whole. But it vanishes almost completely while the number of nuclei is relatively constant. In general, diminutions which are questions of seconds or minutes with the ions are more than questions of hours with the nuclei.

Just as in these cases there is no marked decrease of the number of nuclei while the ions all but go, so I have been unable to find any contemporaneous increase of number; and yet in my experiments with phosphorus and with water nuclei the activities of any generator for the simultaneous production of nuclei and of ions seem to increase and decrease together. I shall be able to state this more definitely at the conclusion of my present experiments on the efficiency of different types of water jets.

Finally, in my "Experiments with Ionised Air" (p. 12), I showed that in case of tests made with the steam jet, nuclei produced by the X-rays in atmospheric air were persistent in like degree with phosphorus and other nuclei. In fact, there was little difference in this respect among the nuclei examined. Nuclei produced in dust-free air, saturated either with water vapour or with hydrocarbon vapour, by the X-rays acting from without, retain the same order of persistence, whereas the ionisation is known to be fleeting. True, rubber stoppers and tubes made up a part of my condensation chamber, but in the case of water nuclei, at least, I can see no objection to this. The entire absence of electric field is always understood.

In all cases, therefore, the electrification vanishes and leaves a nucleus behind, sometimes larger, sometimes smaller. If, in any one of them, the nucleation and the ionisation vanished at the same rate, the case would be good presumptive evidence of their identity. But, to my knowledge, never does this occur. What justification is there, then, to call the phosphorus nucleus an "oxide," or if an oxide associated with ionised air, why does one not find the smaller air nuclei? I should answer that the phosphorus nucleus is the stable product of the initially ionised field. Again, why is phosphorus and dry air a more complicated system than air and water vapour under the action of the X-rays? *Out of both systems* eventually issues a stable nucleation. And why may one attribute to ionised air different condensational properties, according as positive or as negative ions are in question, without having first established that the corresponding air nuclei do not differ in size sufficiently to account for the condensational difference observed? Why may one condense on a nucleus from which the soul has fled and still be permitted to call it an ion? Why, indeed, does the nucleus persist after the ionisation has vanished; why does one not get back to dust-free air? My answer would be as in the case of phosphorus. As to water nuclei, I am much in doubt ever since I have been able to arrest the finest fog particles for examination whether the nucleus from shattered water is mere water dust. It seems to me, therefore, that electrification, if present simultaneously with nucleation, is an incidental accompaniment with no immediate bearing on the condensation produced, and for this reason I have in the above endeavoured to account for the nucleus at the outset chemically. Carl Barus.

Brown University, Providence, U.S.A.

I do not think that any worker with ions or with condensation nuclei who may have read the papers on "Experiments with Ionised Air" and on "The Structure of the Nucleus" will consider my criticism unjust.

The latter part of the letter requires some reply. According to Prof. Barus, in all cases studied by him the nuclei were distinct from the ions, persisting long after the ionisation had disappeared. All that this proves is that he has not yet succeeded in observing condensation upon the ions, but only upon nuclei of another kind. According to my experiments (*Phil. Trans.*, vol. cxciii. pp. 289–308, 1899), a fourfold supersaturation is required to cause condensation on the negative ions, a sixfold being required for the positive ions. To get such high supersaturations as these an exceedingly rapid expansion is required, and it is probable that the apparatus used by Prof. Barus is unsuitable for the purpose. In the presence of any considerable number of nuclei requiring inappreciable supersaturation (as persistent nuclei always do) to cause water to condense upon them, it must be particularly difficult to reach the supersaturation necessary for condensation upon the ions. Such persistent nuclei always were present in Prof. Barus's experiments; his failure to get condensation upon the ions was thus to be expected. His results have no bearing, therefore, upon the interpretation of my experiments on the action of the ions produced by X-rays and similar agents on condensation (for in these experiments nuclei more persistent than the ions were absent), nor of the experiments upon the charge carried by the ions made by Prof. J. J. Thomson (*Phil. Mag.*, vol. xlvi. p. 528, 1898, and vol. v. p. 346, 1903) and by Dr. H. A. Wilson (*Phil. Mag.*, vol. v. p. 429, 1903) with the same form of rapid-expansion apparatus as was used by me.

I have never been able to produce by the action of X-rays nuclei other than the ions, but possibly very intense radiation may do so, as ultra-violet light certainly does.

C. T. R. Wilson.

Cavendish Laboratory, November 23.

Weather Changes and the Appearance of Scum on Ponds.

Some experiments which I have been making during the last year seem to bear very directly upon the interesting phenomenon described by "Platanus orientalis" in your issue of November 5. These experiments show that numerous solid substances suspended or dissolved in water have, by virtue of their surface-tension relations, a marked tendency to accumulate at any surface separating water from gas (*vide Proc.* Roy. Soc., August). Hence, by merely passing a stream of air-bubbles through solutions or suspensions of certain solids in water, it is possible to effect a considerable concentration of the dissolved or suspended solid in the upper layers of the liquid. Each bubble carries with it to the surface a load of solid particles, and leaves many of them floating there either as an ultra-microscopic "pellicle" or as a visible "scum." If a bubble is very minute, its load may be so great in relation to its volume that it may be entirely unable to rise, or may even sink. If, in these circumstances, the barometric pressure be diminished, the volume of the bubble increases in greater proportion than the surface-area, and therefore than the maximum load, with the result that numerous bubbles previously unable to ascend at once begin to rise towards the surface. If, during their ascent, the barometric pressure be sufficiently increased, at once they sink. If a vessel of water containing a sediment of sulphur or calcium soap, &c., be exposed to a sufficiently diminished air-pressure, the whole of the sediment will be seen to rise to the surface, the minute air-bubbles with their coating of solid acting like so many "Cartesian Divers."

In every ordinary pond gas-bubbles of various kinds are constantly being formed by the action of micro-organisms; in nearly every pond various solid substances, both organic and inorganic, possessing the required surface-tension relations, are present both in the mud and in suspension. The gas liberated will be constantly bringing scum-forming material to the surface, whether it rises in large masses or in small bubbles. Either a fall in the barometric pressure, or a rise in temperature, or an increase in the activity of the gas-producing organisms should therefore result in increase of the scum. It must, however, frequently happen that the scum is swept to one side by the wind or sunk by various mechanical disturbances.

It would be extremely interesting to learn whether by "decided change in the weather" your correspondent means a change attended by a falling barometer.

Pembroke College, Oxford. W. Ramsden.

The "Affenspalte" in Human Brains.

Will you kindly allow me the privilege of using your columns for the following note? In a recent number of the *Anatomischer Anzeiger* Prof. Elliott Smith published a most interesting forecast of an extensive work which he has in hand, dealing particularly with the occurrence in human brains of an occipital operculum; this occurrence had been considered previously as very exceptional, but Prof. Elliott Smith is able to show that this is far from being the case.

The presence of such an occipital operculum implies the existence, in the cerebral hemisphere possessing it, of a sulcus, called by Prof. Elliott Smith the sulcus lunatus, which is strictly comparable to, if not absolutely identical with, the "Affenspalte" so typical of the brains of Simiidæ and Cercopithecidæ.

The examination of cerebral hemispheres of representatives of the lower human races is naturally suggested, and the aborigines of Australia, from several points of view, seem particularly appropriate in this connection. Following up Prof. Elliott Smith's suggestion, I have examined the brains of the aboriginal natives of Australia in the Cambridge Anatomical Museum. As a result, four out of eight hemispheres show plainly the sulcus lunatus and occipital operculum. In one case only is the condition symmetrical in the two hemispheres. The smallest brain of the four bears a sulcus lunatus and operculum on one hemisphere only. Where the sulcus lunatus is interrupted, compensation seems to be provided by deepening of the inferior occipital sulcus.

A Chinese brain in my possession has in each hemisphere a sulcus lunatus.

I shall be much obliged if you can kindly place these observations on record. W. L. H. DUCKWORTH.

November 27.

The Rate of Nerve Impulses.

DR. ALCOCK, in his recent paper at the Royal Society, finds the rate of transmission of nerve impulses in man to be 66 metres per second. Sir Michael Foster, in his "Physiology" (1888, part i. p. 76), gives it as 33 metres per second. The difference is considerable, and places us in a dilemma:—(1) either Sir Michael Foster or Dr. Alcock is widely wrong; or (2) the rate of transmission has become greatly accelerated during the last fifteen years. Of the two, the latter seems to me the simpler explanation.

W. R. GOWERS.

The Leonids of 1903.

OBSERVATIONS were begun on November 15 at 17h. 57m. and continued until daylight rendered further watching useless. In the first five and a half minutes twenty meteors appeared, all but two of which were Leonids, so that the hourly rate of the latter was 200. This period seems to have been about the time of maximum, judging from the results of other observers. Shooting stars now began to diminish in frequency, as the sky was brightening as day approached, but in the half hour comprised between 17h. 57m. and 18h. 35m. (deducting time spent in recording) thirty-six were seen, thirty-four being Leonids. Beyond 18h. 35m. the twilight was too strong to expect to detect meteors, and though the look-out was continued until 18h. 57m. no more appeared.

The display was certainly very fine, Leonids shooting one after the other in various parts of the heavens, the effect being heightened by the crescent moon and Venus, shining resplendently side by side in the south-east. Most of them were bright, the average magnitude being 1 or a little greater. As is usual with the meteors of this shower, they moved swiftly and left streaks. The prevailing colours were blue and yellow.

The radiant point, as indicated by ten registered paths, was at $148° + 22°$.

The chief observed Leonids were:—

November 15.

Time h. m.		From		To		Mag.
18 $7\frac{1}{2}$	...	$139\frac{1}{4} - 6$	...	$138 - 9$	...	>1
18 $10\frac{1}{2}$	...	$174 + 20\frac{1}{3}$	...	$179\frac{1}{2} + 19\frac{3}{4}$	...	= ♃
18 20	...	$110 + 9$	...	$106\frac{1}{2} + 7$	...	> Sirius
18 $34\frac{1}{2}$	...	$139\frac{1}{2} + 33\frac{1}{2}$	...	$132\frac{1}{2} + 38\frac{1}{2}$	...	= ♀

On the following night the sky was watched from 12h. 10m. to 14h., but though it was clear most of the time, only two Leonids were observed, and meteors generally were scarce. On November 18, from 18h. 5m. to 18h. 20m. no shooting stars appeared.

These two latter watches bring out an important fact, namely, that the shower very rapidly declined in strength after the maximum had been passed.

Sheffield, November 27. ALPHONSO KING.

ACCOMMODATION OF SCOTTISH SCIENTIFIC SOCIETIES.

IN response to a requisition signed by seven fellows, a special meeting of the Royal Society of Edinburgh was held on the afternoon of Thursday, November 26. There was a large attendance. The president, Lord Kelvin, occupied the chair; and Sir John Murray, seconded by Dr. John Horne, moved the following resolution, that

"This meeting of the Fellows of the Royal Society resolves to instruct the council to enter into formal communication with the other scientific societies having their headquarters in Edinburgh with the view of concerting measures for obtaining the use of the Royal Institution building wholly and exclusively for Scottish scientific societies."

The resolution was also supported by Prof. Cossar Ewart, Prof. Chiene, Dr. Munro, Dr. Buchan, Prof. Hudson Beare, Sir James Russell, and Prof. Chrystal. The last named, in his official capacity as secretary, referred to the history of the relation between the society and the Board of Manufactures for Scotland; while most of the other speakers spoke from the point of view of the various other societies of which they were members, such as the Royal Scottish Geographical Society, the Royal Society of Arts, the Meteorological Society, the Royal Physical Society, the Geological Society, the Mathematical Society, &c.

All who spoke were unanimous in their opinion as to the importance of the scientific societies having their rooms and libraries in one building. The advantages of such a combination are evident to all interested in the progress of science, and need not be enlarged on in these pages. But there are features peculiar to the present movement which deserve to be widely known. These were touched upon and in many cases emphasised by Sir John Murray and those who supported him.

One of the most striking architectural ornaments in Princes Street is the Royal Institution, erected in 1828. The Royal Society has always occupied the west wing of the building, and the rest is at present mainly devoted to art in the form of a statue gallery and schools of art. Several rooms are used by the officials of the Board of Manufactures, the reorganisation of which forms the subject of an important report recently made by a departmental committee specially appointed. So far as this report has to do with the Royal Society, it is in practical agreement with the claims advanced by that body, as given in the evidence of the secretary, Prof. Chrystal. These were that the society should have increased accommodation for its growing library, and should sit rent free and in perpetuity. It was pointed out by witness after witness before the committee that the building is unsuitable for art, and the committee accordingly recommends the construction of a new building for national galleries and art schools. Should the people of Scotland carry this recommendation into effect, the representatives of art will evacuate the Royal Institution, and the question will arise as to the best use to be made of the rooms. The Royal Society cannot effectively occupy the whole building, and it is under these conditions that Sir John Murray brings forward his plan for the concentration of scientific effort in the capital of Scotland. Very little internal change in the building would make it suitable for the purpose, and there is a large central hall which would serve admirably for scientific meetings of wider scope or of a popular character.

An "equivalent grant" to Scotland of 2000*l.* dates from the Union of the Parliaments, and the Board of Manufactures was appointed shortly after that time to

manage this grant and perform other incidental duties. At first this grant was devoted to the encouragement of woollen and linen manufactures, and of fisheries. Grants have also been made for scientific purposes; but latterly the money has been expended in the interests of archæology and art. In his evidence before the departmental committee, Sir Francis Mowat said that the treasury would gladly give 40,000*l.* in lieu of the 2000*l.* a year. This offer, Sir John Murray thought, should be accepted at once; for it is this 2000*l.* a year (from which science now gets no aid), which has again and again stood in the way of Scotland getting on the estimates for any scientific purpose. Were this done, the 40,000*l.*, together with other funds which have accumulated from the 2000*l.* and are now in the possession of the Board of Manufactures, could be used for building a national gallery and school of art. Although part of this sum should rightly be devoted to science, Sir John Murray was sure that all scientific men would willingly give up this right if they obtained the present Royal Institution building for their various societies.

There is not the least doubt that such a scheme would economise scientific effort, encourage scientific research, and make possible that unity and solidarity of action which is all important whenever any general scientific object is aimed at.

C. G. K.

SOME ILLUSTRATIONS OF THE MINUTE IN NATURE.[1]

THIS book is intended to bring a somewhat technical and special subject, but one of great beauty and interest, directly before the general reader. The author dissociates his subject from all scientific methods and processes, and even from the instruments by which the work is done, and is content to direct the reader of fair intelligence simply to results. These are on the whole fairly selected, and presented, pictorially and descriptively, with ability. It is not a book for microscopical workers, however elementary, for it is a mere selection of objects likely to awaken interest in minds unfamiliar with the minute in nature. As might be anticipated, it is only low and moderate magnifying power that is employed in these "revelations," but the photomicrographs are good, and give correct impressions of the objects to those who have never seen them, or are unfamiliar with the use of lenses in the study of nature.

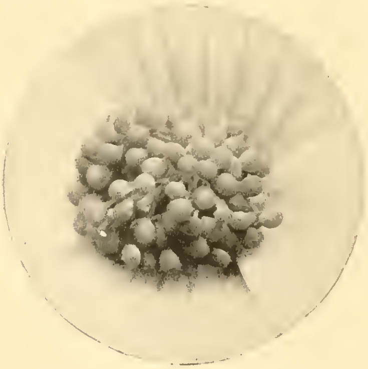


FIG. 1.—The Central Portion of a Male Begonia Flower. From "Minute Marvels of Nature," by J. J. Ward.

A great deal of space and labour is spent in dealing with the beginnings of plant life and the internal structure of plants. The illustrations devoted to the former purpose are not always competent, as that on p. 16 shows, which was intended to give an illustration of diatoms in their natural state. To a reader having no idea of what diatoms are, no enlightenment can be obtained from this photomicrograph. Many of the illustrations of diatoms are well done, and it is not at all probable that the reader will obtain from any other source photographs of the elaborate artificial arrangement of diatoms in geometric designs as they are given in this book.

FIG. 2.—Pollen-grains falling from the Stamens of one of the Mallow Flowers (magnified). From "Minute Marvels of Nature," by J. J. Ward.

The photographs illustrating plant structure are admirable, and will undoubtedly appeal to the general reader, and at the same time do much to awaken his interest in the hidden things that the microscope so readily reveals.

There is a good chapter, well illustrated, on pollen or flower dust, while some admirable illustrations and instructive writing are given the reader on the subject of insects' eggs. Some of these illustrations are of the first quality, but more care and detail would have greatly enhanced the usefulness of others of no little value in the efficient illustration of the subject. We may specialise Figs. 87 and 89, which were either inefficient photomicrographs or else processed so badly as to have made rejection a necessity. The figure giving the eggs of the small copper butterfly is excellent.

[1] "Minute Marvels of Nature," being some revelations of the microscope exhibited by photomicrographs taken by the author, John J. Ward. Pp. xxiv+272. (London: Isbister and Co., Ltd., 1903.) Price 7*s.* 6*d.*

The chapter on animal parasites is of interest, and will be eagerly perused by those for whom this book is written; so will the illustrations and descriptions of insect weapons and tools, although this chapter might with great ease have been made more popular by many added illustrations from familiar sources.

The book is well printed on good paper and admirably bound. It would make a useful and desirable present, and will, we believe, be read with pleasure by the general public, who will find that it opens a new world of facts and suggestions to them. D.

M. TSYBIKOFF'S JOURNEY TO LHASSA.

IN the latest number of the *Izvestia* of the Russian Geographical Society (1903, iii.) there is a very interesting paper, by M. G. Ts. Tsybikoff, on his journey to Central Tibet and his stay at the city of the Dalai-lama, Lhassa, the unattained goal of so many European travellers. M. Tsybikoff is a Russian Buryate by birth, and a Lamaite by religion, who studied at the Oriental faculty of a Russian university, and after having carefully prepared himself for this journey went to Tibet, as so many Buryate pilgrims do. He stayed on his way through Mongolia in two of the most renowned Mongolian monasteries, and on August 1, 1900, entered the holy precincts of Central Tibet without any difficulty. It was on the northern slope of the Bumza Pass, on the San-chu River. From this spot the caravan travelled south-westwards through the broad and open, extremely high and dry valleys of Central Tibet, where cereals are nevertheless grown by means of irrigation, and on August 16 they entered the holy city, after a three months' journey from the Gumbum Monastery, and a 370 miles' journey through Tibet proper.

At Lhassa M. Tsybikoff stayed more than twelve months, until September 23, 1901, and from that city he made an excursion so far as Tsetan, or Chetan, visiting, besides the three great monasteries situated round Lhassa—Braibun (8500 monks), Sera (5000 monks) and Galdan (2000 to 2500 monks)—also the monasteries of Dashi-lhunbo (170 miles from Lhassa, on the right bank of the Brahmaputra) and Sam-yai, on the left bank of the same river, about 67 miles south-east of Lhassa, one of the oldest in Tibet, as it was founded in the ninth century. He also visited the towns Shiha-tse, Chan-tse, and Tsetan.

The descriptions which the Russian traveller gives of Lhassa and its sanctuaries, as well as of the monasteries already mentioned, the population, its composition and its ways of living, the Government and administration, and the climate of the country—meteorological observations were made thrice a day without interruption for 235 days—are extremely interesting. The estimates of population hitherto given have been very much exaggerated, and M. Tsybikoff takes the number as not exceeding two and a half millions, out of whom one million are living in the two provinces U and Tsan. Lhassa has no more than 10,000 inhabitants, two-thirds of whom are women, its population having been overestimated on account of the 15,000 to 16,000 monks staying in the three above-named monasteries and the numbers of pilgrims.

During his stay at Lhassa M. Tsybikoff made an extremely valuable collection of 317 volumes (now in the hands of the St. Petersburg Academy of Sciences) o Tibetan books on philosophy, medicine, astronomy, history and geography, as also of prayers and incantations, written by the most renowned lamas for the last nine centuries.

The paper is illustrated by nine excellent photographs, representing views of Lhassa, the palace of the Dalai-lama, and the monasteries of Galdan and Dashi-lhunbo. The pictures are taken from the collection of M. Norzunoff, a Kalmyk pilgrim who also was at Lhassa in the same year, and brought back forty-five photographs. M. Tsybikoff's collection (twenty-one photos) reached the Russian Geographical Society after the views mentioned above had been printed.

Those who are interested in Tibet will be glad to know that, besides the diary of the Buryate Zayaeff, who visited Central Tibet in the eighteenth century, the diary of the Kalmyk Baza-bakshi Menkejieff was published in 1897, with a Russian translation by Prof. Pozdnéeff.

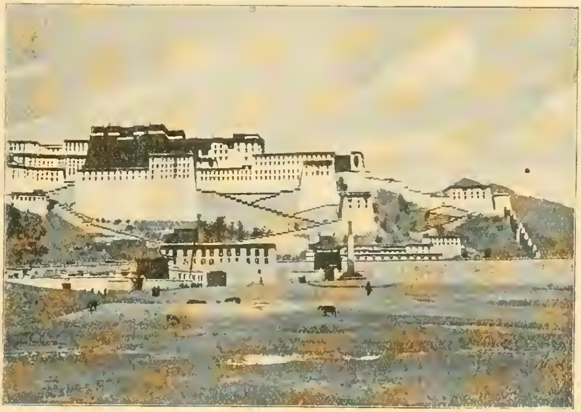

Fig. 1.—Bodala, the palace of the Dalai-lama at Lhassa, seen from the south. (It is built on the cliff Mar-bo-ri, which rises above the plain of the Ui-chu River, about two-thirds of a mile from the city itself).

ANNIVERSARY MEETING OF THE ROYAL SOCIETY.

AT the anniversary meeting of the Royal Society on Monday, the officers and council for the year were elected, the report of the council was read, and the president delivered his address. In the following list of the elected council, the names of new members are printed in italics :—

President, Sir William Huggins, K.C.B.; Treasurer, Mr. A. B. Kempe; Secretaries: Prof. Joseph Larmor and *Sir Archibald Geikie*; Foreign Secretary, Mr. Francis Darwin. Other Members of the Council: *Mr. G. A. Boulenger*, *Prof. J. R. Bradford*, Prof. H. L. Callendar, *Mr. F. W. Dyson*, Prof. H. B. Dixon, Sir Michael Foster, K.C.B., *Prof. P. F. Frankland*, *Sir Robert Giffen, K.C.B.*, *Prof. W. D. Halliburton*, *Dr. E. W. Hobson*, Prof. J. W.

Judd, C.B., Prof. G. D. Liveing, Prof. A. E. H. Love, *Mr. Adam Sedgwick, Dr. W. N. Shaw*, Capt. T. H. Tizard, R.N., C.B.

The report of the council refers, among other matters, to the work of the National Physical Laboratory and the scientific results obtained, the International Association of Academies, the International Catalogue of Scientific Literature, International Aëronautics, and sleeping sickness.

In February last, Lieut.-Colonel Bruce, F.R.S., went to Uganda to study sleeping sickness, with Dr. Nabarro as bacteriologist. Soon after their arrival, Dr. Castellani, who was then in Uganda, reported to Colonel Bruce that during the past five months he had observed trypanosomes in the cerebro-spinal fluid of cases of sleeping sickness, and a telegram was received from Colonel Bruce in April stating that he considered it very probable that a trypanosome was the cause of the disease.

Since then a report entitled "Progress Report on Sleeping Sickness in Uganda" has been received and published as No. 2 Report of the Sleeping Sickness Committee.

Colonel Bruce returned to England in September, bringing with him a further report which adduces evidence that—

(1) Sleeping Sickness is caused by the entrance into the blood, and thence into the cerebro-spinal fluid, of a species of trypanosoma.

(2) This species is probably that discovered by Forde and described by Dutton from the West Coast of Africa, and called by him *Trypanosoma Gambiense*.

(3) The so-called cases of trypanosoma fever, described from the West Coast, may be cases of Sleeping Sickness in the earliest stages.

(4) Monkeys are susceptible to Sleeping Sickness, which in them produces the same symptoms, and runs the same course, whether the trypanosomes injected are derived from cases of so-called trypanosoma fever, or from the cerebro-spinal fluid of cases of Sleeping Sickness.

(5) Dogs and rats are partially susceptible, but guinea-pigs, donkeys, oxen, goats, and sheep, up to the present, have shown themselves absolutely refractory.

(6) The trypanosomes are transmitted from the sick to the healthy by a species of tsetse fly, *Glossina palpalis*, and by it alone.

(7) The distribution of Sleeping Sickness and *Glossina palpalis* correspond.

(8) Sleeping Sickness is, in short, a human tsetse fly disease.

In the course of his address, the president referred to the portrait of Lord Rayleigh, painted by Sir George Reid, which was formally presented to the society at Monday's meeting, and to the retirement of Sir Michael Foster, the senior secretary. A large part of the address was devoted to suggestions which have been made to affiliate important special or local societies with the Royal Society. A committee appointed to consider the question some time ago decided that the Royal Society, both as to its administration and work, should remain as heretofore, and not enter into any formal relationship with special societies. Support was, however, given in the address to the need of integration in respect of publications of the Royal and other scientific societies. The joint publication of papers was brought before the council several years ago, but was not received with favour. It has since been found to work successfully with the Royal Astronomical Society, and the opinion is expressed that other societies might arrange for the duplicate publication, in their own *Transactions*, of papers communicated to the Royal Society of special interest to the respective special societies. This plan leaves each society to its complete independence, and does not involve the Royal Society in any obligation which would in any way interfere with its own free administrative working.

The work of this year's medallists was described in the address as follows:—

Copley Medal.

The Copley Medal is awarded to Prof. Edward Suess, For. Mem. R.S., in recognition of his eminent services to Geology, and especially of his original researches and conclusions published in his great work, "Das Antlitz der Erde."

Prof. Suess was for 40 years Professor of Geology in Vienna University, and under his guidance a school of Geology has arisen, which is not surpassed in any country of the world. He has written numerous papers on Stratigraphical and Physical Geology, and has published much valuable palæontological work. The results of many years of study were contained in "Die Entstehung der Alpen," published in 1875. In this book he traced the geological history of the Central European ranges, and applied the results of his inquiry to the problems of mountain formation and surface contours in general. This work was followed, in 1885, by the first volume of "Das Antlitz der Erde," in which the same problems were attacked on a wider field. The second volume was published in 1888, but the first part of the third volume was not issued until 1901. In this great work the study of the changes that have taken place during geological times in the oceans and seas of the globe is combined with inquiry into alterations in the form of the solid surface. Owing to the wonderful grasp of the subject, and the striking originality shown, the work has influenced geological thought to an extent that has seldom been equalled.

Many geologists have distinguished themselves by mastering the geological structure of different countries, small or large, or have devoted their energies to the solution of particular problems; Suess has aimed at giving an explanation of the surface features exhibited by the whole world, founded on an investigation of its geological history. The forms of continents and islands, the distribution and direction of mountain ranges, the profiles, contours, and histories of the great oceans—all are treated by him with a master's hand. "Das Antlitz der Erde" represents the culmination of the Geology of the nineteenth century; as has been most aptly said by Marcel Bertrand in his preface to the French translation, it is the last term of the revolution commenced a century ago by Werner and Hutton.

Royal Medal.

A Royal Medal is awarded to Sir David Gill, K.C.B., F.R.S., for his researches in Solar and Stellar Parallax, and his energetic direction of the Royal Observatory at the Cape of Good Hope.

Sir David Gill (H.M. Astronomer at the Cape Observatory since 1879) is specially distinguished for his researches on the distances of the heavenly bodies, although his other work has covered a large field. He has made four independent determinations of the sun's distance by heliometer observations of Mars (1877), Iris (1888), Victoria (1889), and Sappho (1889), being ably assisted in some of these investigations by others, but undertaking the greater part of the work himself. The four determinations agree wonderfully well in giving a solar parallax very near 8″·80, which has consequently been adopted for general use in national Ephemerides since the beginning of the present century. Incidentally this work gave improved values for other constants of the solar system, especially the lunar equation in the sun's motion; and it suggested that the time had arrived for an entirely new method of observing the places of the planets, which Sir David Gill has since initiated.

He has also determined the parallaxes of eleven stars of the first magnitude, and four stars of larger proper motion; and several similar determinations carried out by others have been inspired by Sir David Gill. And he has discussed the results from a cosmical point of view. In such work he takes a first place among astronomers.

In addition to these researches of the normal type, Sir David Gill, by his energy and enterprise, has placed the Cape Observatory in the front rank; so that for the first time in the annals of Astronomy we have now at length an observatory of the highest class in the Southern Hemisphere. He has brought up to date the current reductions, and has produced several valuable catalogues of stars, in which particular attention has been paid to the elimination of small errors, notably the "magnitude-equation," to

which Sir David Gill was himself the first to direct attention. And he has completely photographed, on a moderate scale, the Southern Hemisphere. The plates were measured in Holland by Kapteyn, who has published the results recently in a valuable work, the "Cape Photographic Durchmusterung," for which Kapteyn received the Royal Astronomical Society's Gold Medal in February, 1902. It may be recalled that on that occasion Kapteyn expressed very warmly his indebtedness to Sir David Gill.

Sir David Gill had a large share in initiating the International Astrographic Chart; he has also been very active in superintending the Geodetic Survey in South Africa.

Royal Medal.

The other Royal Medal is conferred upon Dr. Horace T. Brown, F.R.S., for his work on the chemistry of carbohydrates, and on the assimilation of carbonic acid by green plants.

His memoir (H. T. Brown and G. H. Morris, *Journ.* Chem. Soc., 1893) on the "Chemistry and Physiology of Foliage Leaves" is of value as confirming the rougher work of Sachs on the amount of carbohydrate assimilated per leaf area per unit of time, but especially as being the first thorough investigation into the manufacture and translocation of the various sugars in the green leaf. This paper also contributes to our knowledge of the action of diastase in the leaf; and in this connection may be mentioned the paper on the "Germination of the Gramineæ" (H. T. Brown and G. H. Morris, *Journ.* Chem. Soc., 1890), which is a valuable contribution to the study of diastase and other enzymes.

His Presidential Address to the Chemical Section of the British Association, 1899, gave an account of work of the highest interest to botanists, such as the relation between the amount of assimilation of carbon and the partial pressure of the carbonic acid in the atmosphere, and the rate of absorption of carbonic acid by a leaf, as compared with the absorption by a solution of caustic alkali. These and other points are developed in the memoir on "Static Diffusion of Gases and Liquids in Plants" (H. T. Brown and F. Escombe, *Phil. Trans.*, 1900), which is one of the most important works on assimilation by plants that we possess. In this remarkable essay, Brown develops the principles determining the amount of diffusion from gases and solutions into absorbing surfaces, and shows that leaves conform in the size and number of the stomata to absorbing surfaces of high efficiency.

The earliest important chemical work of Horace Brown was on the influence of pressure on fermentation. He discovered that other gases besides carbonic acid were given off in the fermentation of malt worts and of grape sugar, and that the hydrogen evolved increased as the pressure was diminished. The formation of acetic acid during the fermentation out of contact with air was shown to be due to a direct transformation of the sugar into acetic acid.

In conjunction with Heron and Morris, he made a series of valuable investigations into the nature of starch and its transformations. He showed that the action of malt extract upon soluble starch might be represented by the *successive* removals of maltose by hydration (hydrolysis), the successively formed residues being a series of dextrins.

He was the first to apply Raoult's freezing-point method to the systematic determination of the molecular weights of the carbohydrates, and his measurements showed that soluble starch was much more complicated than the dextrins derived from it, the starch molecule possibly consisting of four complex amylin-groups arranged round a similar fifth group. But later work on dextrinic acid led to the view that the starch molecule is made up of the residues of 80 *maltan* groups and 40 *dextran* groups, linked in ring form through oxygen atoms, and that the maltan portion of the ring is attacked by successive stages of hydrolysis, forming dextrins and finally maltose. The molecular weight of starch cannot be less, according to these experiments, than 32,400.

The investigation of "secondary fermentation" produced by a small quantity of dried hops in beer led to his important work on the chemistry and physiology of foliage leaves, in which he gives reasons for supposing that cane-sugar is the first sugar to be synthesised by the assimilatory processes, and that this is the starting point of the metabolic changes in the leaf.

The discovery of the solution of the cell-membranes of grass seeds by a cellulose-dissolving enzyme secreted in the epithelium led him to investigate the corresponding action on the cell-walls of starch granules in the processes of animal digestion. After exhaustive experiments, he concluded that the cell-walls were attacked by an enzyme pre-existent in the grain.

Davy Medal.

The Davy Medal for the most important discovery in chemistry is awarded to M. Pierre Curie, and Madame Curie, Docteur ès Sciences, for their researches on radium.

The discovery of radium—whether it be regarded from the point of view of the extraordinary properties of that substance, unique in their intensity if not in their kind, or of the undeviating aim and invincible patience with which the clue to its separation has been skilfully followed, or of the extended, even revolutionary, views of the constitution of matter and of the stores and transformations of energy in Nature which the study of its properties is opening up to us—may well be characterised as the most important discovery in chemistry of the present time.

Hughes Medal.

The Hughes Medal is awarded to Prof. Johann Wilhelm Hittorf for his experimental researches on the electric discharge in liquids and gases, extending over a period of more than half a century into the present year.

The results of his work have been published in a series of papers, of which the first, on the electric conductivity of mercury, appeared in *Poggendorff's Annalen* so long ago as 1851, and was followed, in the years 1853 to 1859, by others, giving an account of his masterly investigations of the migrations of the ions in electrolysis. In conjunction with Plücker he took up the examination of the spectra emitted by gases under the influence of electric discharges from an induction coil, and communicated the results to the Royal Society in 1864; and in the ensuing twenty years he published, from time to time, a number of papers on electric conductivity in gases, which have greatly contributed to the advancement of our knowledge of that subject. In 1898 and 1899 he published papers on the electromotive behaviour of chromium and on the passive state of metals, and in the three years of the present century further papers on the rates of motion of the ions.

It is now the jubilee of the publication of his first paper on the last-named subject, a paper which marks an epoch in our knowledge of electrolysis. In that paper, and those which followed it in the next five years, by his careful measurements of the movements of the ions in a great variety of cases, he laid a solid foundation on which subsequent investigators have reared a large superstructure. The view of the constitution of electrolytes, and of chemical compounds in general, to which his research directly led, was so contrary to that in vogue amongst chemists at that time that it challenged opposition, but time has vindicated its accuracy and importance. His researches on electric conductivity in gases have been almost equally fruitful, for they have served as the starting point from which other observers have advanced, and have thus led up to modifications of our ideas of the constitution of matter quite as profound as those suggested by the migrations of the ions.

PROF. ROBERT HENRY THURSTON.

By the death of Prof. Robert Henry Thurston, which occurred with tragic suddenness on his birthday, October 26, the United States has lost its most distinguished engineering professor, and a devoted educationist whom it will be difficult to replace.

He was born at Providence, Rhode Island, in 1839, and was the son of Robert L. Thurston, the founder of the Providence Steam Co. His early training was of that twofold character which has been so much discussed during the last year or two, a collegiate education at the Brown University, where he gradu-

ated C.E., Ph.B., in 1859, and a practical training during the same time in the workshops of his father's firm.

In 1861 he entered the United States Navy, serving from 1861–1865 first as assistant engineer and then as engineer in charge of vessels; this period covered the great Civil War, and the unique experience which Thurston then enjoyed no doubt did much towards turning his mind to experimental research, and probably altered the whole course of his life's work.

In 1865 he was appointed assistant professor of natural philosophy in the United States Naval Academy at Annapolis, and as his chief died a few weeks afterwards, Thurston had entire charge of the department until he resigned the post, in 1871, in order to take up the duties of professor of mechanical engineering in the Stevens Institute of Technology, an office he held until 1885.

It was while he held this chair that Thurston began to make his name known, not only in America, but in Europe; he was a prolific writer on technical subjects, and did much valuable research work in connection with the U.S. Board appointed to deal with the subject of testing metals, notably in the investigation of the properties of the various alloys of copper, tin, and zinc. During this period he also visited Europe as the U.S. Commissioner to the Vienna Exposition of 1873, and on his return published a valuable report.

In 1885 he took up the post which he held until his death, that of director of Sibley College; here he had full scope for his remarkable powers as a teacher and an organiser of scientific education of the most advanced character, and the most eloquent testimony to his success is the extraordinarily rapid growth in the number of students; from a mere handful in 1885, in eighteen years they have increased to nearly 1000, and Sibley College to-day stands in the very front rank of the great technical colleges of the world devoted to the scientific training of the men who are to be the leaders of the engineering profession in all its branches. Much of its success is due to the fact that he was from the first able to win the sympathy and support of the leading engineers of the States, with the result that the Sibley College graduates never find the least difficulty in securing paid posts as soon as they finish their college training.

Thurston altogether wrote some 20 volumes and more than 300 separate scientific papers; his fertility with the pen, when one considers the labours he daily went through as a teacher and director, is amazing, and some of his books bear traces of the haste and pressure under which they were produced.

Of his books, the most noteworthy are the following:—"Friction and Lost Work," "The Materials of Engineering," "A Manual of the Steam Engine," "Steam Boiler Construction," and "A History of the Steam Engine"; these are all in America recognised as standard works, and have found a ready sale also in this country. In fact, Thurston almost attained the same position as was held by Rankine for so many years in this country, and his books were consulted and used by thousands of young engineers scattered throughout the length and breadth of the great Republic.

Thurston was naturally the recipient of many honours; he was the first president of the American Society of Mechanical Engineers, holding office from 1880 to 1883, vice-president of the American Association for the Advancement of Science in 1877, 1878, and 1884, an LL.D. of the Brown University in 1889, &c.; he was twice married, in 1865 to Susan Taylor Gladding (she died in 1878) and in 1880 to Leonora Boughton.

Though Thurston devised several special forms of testing machines, he was not an inventive genius, and he did no work as a constructive engineer. It was as a writer and speaker that he made his influence felt, and how great that influence was will only be fully realised now that he has gone. T. H. B.

SIR FREDERICK BRAMWELL, F.R.S.

THE death of Sir Frederick Bramwell on Monday deprives engineering of one of its most energetic workers, and pure science of one who did much to promote its interests.

Sir Frederick Bramwell was born in London on March 7, 1818, and was apprenticed to one of the old school of mechanical engineers when he was sixteen years of age. After a varied experience he commenced practice on his own account as a civil engineer in 1853, and the following year became a member of the Institution of Mechanical Engineers. He was elected an associate of the Institution of Civil Engineers in 1856; and in 1862 attained full membership.

In 1874 Bramwell was chosen president of the Institution of Mechanical Engineers, and delivered an address in which he appealed to engineers to use to their utmost, and to use fairly, the natural resources at their command. As president of the Institution of Civil Engineers in 1884, he described in his address the chief factors of past progress, and advocated the treatment of large steel forgings by hydraulic pressure in place of steam hammers. He was president of the Mechanical Science Section of the British Association in 1872, and again at Montreal in 1884. He was elected president of the Association for the Bath meeting in 1888, when he delivered an address on the greatness of the works which the engineer creates out of minute beginnings.

Sir Frederick Bramwell received many marks of recognition from public bodies and learned societies. In 1873 he was elected a Fellow of the Royal Society. In 1881, the *Times* relates, he was appointed member of the Ordnance Committee, and in that capacity assisted in the framing of the rules under which iron and steel for the construction of large ordnance are tested before acceptance. After serving on the council and as a member of the board of management he was, on the retirement of Sir William Bowman in 1885, made honorary secretary of the Royal Institution. Always cordially lamenting the lack of facilities for technical education in his youth, he was a warm supporter of the movement for its advancement in this country. On the foundation of the City and Guilds of London Institute he was appointed by the Goldsmiths' Company one of its representatives on the governing body. A knighthood was conferred upon him in 1881, and a baronetcy in 1889. He received the honorary degree of D.C.L. from the Universities of Oxford and Durham, and that of LL.D. from Cambridge and McGill.

NOTES.

PROF. LUDWIG BOLTZMANN has been elected honorary member of the Moscow Academy of Sciences.

THE deaths are announced of Prof. Heinrich Moehl, director of the meteorological station at Cassel, at the age of seventy-one, and Dr. Nagel, formerly professor of geodesy in the technical high school at Dresden.

THE next meeting of the American Association for the Advancement of Science, and affiliated societies, will be held at St. Louis during convocation week beginning on

December 28, under the presidency of the Hon. Carroll D. Wright, U.S. Commissioner of Labour and president of Clark College.

THE Decimal Association has taken steps to introduce into the House of Lords early next session a Bill for the compulsory adoption of the metric weights and measures throughout the United Kingdom. The first reading of the Bill will be moved by Lord Belhaven and seconded by Lord Kelvin. If the measure passes the House of Lords, it will be brought before the Commons at the first possible moment, and it is hoped that a sufficient expression of public opinion will be forthcoming, at the time when the question is being debated, to convince the Government that they will do well to make it their own Bill.

WE have received a circular, the fifth, from the permanent committee of the International Congress of Botany, the second session of which is to be held at Vienna in 1905. At the Paris Congress, in 1900, the board of management on that occasion was constituted a permanent committee so that the congress might be in a position to communicate with the promoters of the Vienna meeting with a view to ensure complete success. The circular gives full information of the steps taken by the permanent Paris committee in the matter of botanical nomenclature, and describes the principles by which their discussions on this subject have been governed. All communications referring to the congress should be addressed to the general secretary, Dr. A. Zahlbruckner, Vienna, I., Burgring 7.

THURSDAY next, December 10, will be the 300th anniversary of the death of William Gilbert. In commemoration of this tercentenary the Mayor and other representatives of the Borough of Colchester will attend the meeting of the Institution of Electrical Engineers on Thursday next to receive a historical picture representing Dr. Gilbert in the act of showing his electrical experiments to Queen Elizabeth and her Court, which will then be presented by the Institution to the Borough of Colchester, where Gilbert was born in 1544, and died in 1603. At the conclusion of the presentation an ordinary general meeting will be held, at which a paper on the slow registration of rapid phenomena by strobographic methods: the "ondographe" and "puissancegraphe" (wave recorder and power recorder), will be read by M. E. Hospitalier, president of the Société Internationale des Électriciens. If time permit, a paper will also be read on the magnetic dispersion in induction motors, and its influence on the design of these machines, by Dr. Hans Behn-Eschenburg.

IN the *Journal de Physique* M. C. Maltézos discusses the sand ripples produced both by wind and water in connection with the theory that they represent the position of nodal lines produced by the interference of direct and reflected waves. This theory is supported by the author's observations made at Phalara (Attica), and a similar explanation is given of the agglomerations of pebbles which occur on many beaches. The phenomena are easily observed by anyone residing near the sea-shore, and an interesting feature is that ripples are formed in the sand even at depths of two or three metres.

PROF. A. RIGHI, in a paper read before the R. Accademia delle Scienze dell' Istituto di Bologna on May 24, describes experiments upon the electric charge generated by X-rays upon metals *in vacuo*. He begins by describing experiments confirming those of Curie and Sagnac, who proved that metals under the action of X-rays give off negative electrons or kathode rays, acquiring in consequence a positive charge which may become considerable if the pressure, and in consequence the ionisation, of the surrounding air be low enough. He next describes comparative measurements of the potential thus acquired under identical conditions by various substances. The last section treats of the variation of the potential acquired by the metal exposed to the X-rays, as its distance from the electrode facing it is varied.

IN the *Scientific Transactions* of the Royal Dublin Society, Mr. Arthur W. Conway, in a short note of four pages, discusses the fundamental equations of electrodynamics, and points out the difficulties attaching to existing theories when radiation is taken into account. The author proposes a system, consisting of a modification of Helmholtz's theory, which he considers is free from the objections attaching to Levi Civita's system. The equations assumed agree with the known relations for electrostatic phenomena, whilst for slow motions they reduce to those given by Helmholtz, which account for the phenomena of electric currents.

MR. J. MORROW publishes in the *Philosophical Magazine* some experiments on the determination of Poisson's ratio by means of a new instrument for measuring the lateral contractions of tie-bars. The instrument has two screws which touch the bar at the points between which the contraction is to be measured, and when the specimen is extended longitudinally the relative displacement of these screw-ends is determined optically. With this instrument values of Poisson's ratio were found for steel, cast iron, wrought iron, brass and copper, agreeing very well with Stromeyer's results.

DURING his exploration of Lake Aral in the years 1900 and 1901, M. L. N. Berg made the very interesting observation that this lake, which had been rapidly decreasing during the years 1850 to 1885, began slightly to increase in 1891. The level was raised during the years 1891 to 1901 by an average of 20 cm. every year. It appears now that during his exploration of Lake Balkhash, which he visited last summer, M. Berg found that this lake also, which was formerly drying up very rapidly, has begun lately to increase. On all sides poplar trees and bushes submerged to some extent are to be seen, while several peninsulæ, like Bai-kabyl, have become islands, and the road from Vyernyi to Karakol is now under water. The waters of the lake are extremely poor in animal life. The explorers found only two species of fishes—one of them the *Perca schrenckii*, special to this lake—while "the bottom of the lake is a real desert—no molluscs, not one worm." The plankton of the lake is, on the contrary, very rich in fresh-water forms. M. Berg found, moreover, to his great astonishment that the water of the lake in June last was quite fresh, along both the southern and the northern shores. As the Balkhash has no outflow, this fact is of special interest.

DR. A. E. WRIGHT AND CAPTAIN S. R. DOUGLAS show by a series of ingenious experiments that the fluids of the blood play an important *rôle* in connection with phagocytosis, the absorption and destruction of bacteria by certain of the white cells of the blood. By mixing bacteria with the white cells of the blood obtained by centrifuging and adding blood serum (*a*) unheated, *i.e.* in the natural condition, (*b*) heated to 60°–65° C. for ten to fifteen minutes, it is found that, under the same conditions, phagocytosis is much more active in the presence of the unheated than of the heated serum. The heating appears to destroy some

activating substance in the serum, the heated serum behaving as a simple diluent, like physiological salt solution (*Proc.* Roy. Soc. Lond., vol. lxxii. p. 357).

The October number of the *Emu* contains the photograph of a subadult Australian barn-owl in which large bunches of the nestling down are retained on the legs, thus communicating to the bird a most remarkable appearance.

The osteology and affinities of the kingfishers form the subject of an article in the October number of the *American Naturalist* by Dr. Shufeldt, who arrives at the conclusion that these birds are probably nearly related to the cuckoos, bee-eaters, and jacamars, although further investigations into the morphology and life-history of all these groups are necessary before these complicated relationships can be properly defined.

An interesting addition to the British marine fauna is recorded in the November issue of the *Zoologist*. Until 1899, when it was discovered on the coast of Brittany, the giant goby (*Gobius capito*), a fish attaining a length of 9 or 10 inches, was believed to be confined to the Mediterranean. As the result of a careful search of the rock-pools last summer, Mr. F. Pickard-Cambridge has demonstrated its comparative abundance on the Cornish coast. In the same journal Mr. P. Podmore describes and figures some fertile hybrids bred from the ring-dove (*Columba palumbus*).

The study of animals from the point of view of adaptation to their surroundings is now the fashion. The October number of the *American Naturalist* contains the first of a series of three or four articles written at the suggestion of Prof. H. F. Osborn on the adaptation of mammals to aquatic, arboreal, fossorial, and cursorial habits. Prof. Osborn states that a number of advanced students have undertaken the necessary investigations, and that the results are of great interest, and in some instances novel. The first of the series, by Mr. R. C. Osburn, deals with adaptations to an aquatic existence. It is pointed out that the extent to which this adaptation has been carried indicates the relative date at which an aquatic or semi-aquatic life was commenced. Most aquatic mammals have depressed and expanded tails, but in the musk-rat and Potamogale this organ is compressed. The latter animal, at any rate, swims, like a newt, by the aid of its tail, to which the hind-limbs are closely pressed; consequently there is no need for webbed feet. Kükenthal's theory that the increased number of phalanges in the flippers of cetaceans is due to the development of double epiphyses, one of which forms an additional phalange, is considered to be probably true. The fact that toothed cetaceans display indications of descent from an armoured ancestor, while the whalebone whales probably trace their descent from a fully haired form, seems to support the diphyletic origin of the two groups.

Pamphlet series No. 25, issued by the Imperial Department of Agriculture for the West Indies, contains a paper on ground nuts in the West Indies, by Mr. W. G. Freeman, until recently the scientific assistant to the Department. Hitherto, although ground nuts are easily grown in the islands, no attempt has been made to cultivate them on a sufficiently extensive scale to supply even local requirements, and quantities have consequently had to be imported. A summary of the results of the experiments on the cultivation of seedling and other canes at the experimental stations at Barbados, 1903, is given in No. 26 of the same series of publications. There were twenty-two fields of canes under experimental cultivation on nine estates situated in typical localities, the canes in each case being treated in exactly the same manner as the other canes on the estate. The best all-round cane proved to be the Barbados seedling, B 208, the second place being taken by B 147, the average quality of its juice being fair.

The reintroduction of cotton growing into the West Indian Islands has soon been followed by the appearance of a destructive pest, the cotton worm or caterpillar—*Aletia argillacea*—which is causing considerable anxiety, as it strips a whole field in a single night. It is affecting Barbados, Montserrat, Antigua, and St. Kitt's-Nevis. The officials of the Agricultural Department are actively engaged in devising methods for efficiently coping with the evil.

Dr. A. Freiherr von Bistram has reprinted from the *Berichte* der naturforschenden Gesellschaft zu Freiburg im Breisgau his paper on the dolomite region of Lugano. It is accompanied by an excellent coloured geological map on the scale of 1 : 50,000, and the author has occasion to praise the contoured maps of the Italian Government, which, on this large scale, and with well-marked footpaths, have proved of service to so many geologists. The most striking feature of the district is the great east-and-west fault dividing the Triassic beds from the crystalline rocks on the north. The dolomite is thickened locally by repetition through earth-movements, after the fashion made familiar to us by the work of Dr. Ogilvie-Gordon and others, but the similarity of the strata prevents adequate mapping of the details. The style of the author enables one clearly to realise the landscapes, as in his picturesque description of the Val Solda. The obliquity of the axis of the Lake of Lugano to the structural folding of the district leads him to assign to it a glacial origin. The author lays stress on the primary differences in the strata deposited in neighbouring areas, as affecting the manner of their subsequent deformation. His notes on the sections actually visible make the paper especially useful to subsequent visitors, and some of his criticisms affect the published maps of the Swiss Geological Survey.

The *Scientific American*, in its issue for November 14, publishes a very complete and excellently illustrated account of modern printing methods, machines and appliances.

Messrs. Macmillan and Co., Ltd., have issued part iv. of "A School Geometry," by Messrs. Hall and Stevens. The booklet runs to twenty-eight pages, and contains the substance of Euclid Book ii., together with Book iii., Props. 35–37. Its price is 6*d*.

Messrs. Longmans, Green and Co. have just published a small work on "The Analytical Chemistry of Uranium," by Mr. H. Brearley, which contains a mass of information relative to the determination of the metal in its ores and in commercial products. The material is divided into four chapters, dealing respectively with the modes of estimating uranium, the estimation of uranium as phosphate, the separation of uranium, and the analysis of uranium ores.

Messrs. Charles Griffin and Co., Ltd., have published the twentieth annual issue of the "Year-book of the Scientific and Learned Societies of Great Britain and Ireland." The publication forms a record of the work done in science, literature and art during the session 1902–1903 by a large number of societies and Government institutions. The information has been compiled from official sources, and should consequently be quite trustworthy. We notice that no details of the Geographical Association are given, or of the Association of Science Masters in Public Schools.

The determination of vapour densities at high temperatures by application of the diffusion method of Bunsen is discussed in a paper by Prof. Emich communicated to the Vienna Academy. For one and the same gas at different temperatures the time of diffusion of a given volume should be proportional to the square root of the absolute temperature. Experiments with tubes of porcelain, platinum, and iridium show that this requirement is approximately fulfilled, and investigations on diffusion are now being carried out up to a temperature of 2000° C.

According to Mr. W. Ackroyd, colour changes are frequently brought about by the action of radium rays. These changes have been examined by embedding a radium bromide tube in the substance experimented upon. After a few hours sodium chloride becomes orange or buff coloured, potassium chloride becomes violet but returns to its original colour very quickly after removal of the exciting cause. Sodium bicarbonate and potassium metabisulphite are changed to amethyst colour after twenty-four hours' exposure.

We have received the second number of vol. i. of the *Journal de Chimie physique*, published under the direction of Prof. Guye, of Geneva. The number contains two interesting papers, one by Prof. Duhem on the eutectic and transition points of binary mixtures which give rise to mixed crystals, the other by Prof. Guye on the electrolysis of alkaline chlorides. The reviews of current physicochemical literature which form the second part of the publication are exceedingly well written, and the papers reviewed are, moreover, of quite recent publication, a statement which cannot be made of many abstracts in other physicochemical journals.

In the November issue of the *Moniteur Scientifique* M. Combes discusses the various attempts which have been made to obtain the diamond artificially. Against the common supposition that the diamond can only be produced at high temperatures, the author cites several observations which seem to indicate that natural diamonds, at any rate, cannot have been formed under such conditions. The hypothesis that high pressures are necessary for the artificial production of diamonds is not in accord with actual experimental facts, and the author arrives at the conclusion that in the experiments of Moissan the pressure plays no essential part, and that the optical properties and the analysis of the crystals obtained by this chemist do not warrant the conclusion that these are to be regarded as diamonds.

The additions to the Zoological Society's Gardens during the past week include a Bonelli's Eagle (*Nisaëtus fasciatus*), European, presented by Mr. G. H. Baxter; a Matamata Terrapin (*Chelys fimbriata*) from Guiana, presented by Mr. E. Bieber; a Yellow-fronted Amazon (*Chrysotis ochrocephala*) from Guiana, a Lesser Sulphur-crested Cockatoo (*Cacatua sulphurea*) from Moluccas, a Common Buzzard (*Buteo vulgaris*), European, deposited; an Ourang-outang (*Simia satyrus*) from Borneo, purchased.

OUR ASTRONOMICAL COLUMN.

Astronomical Occurrences in December:—

Dec. 3. 6h. 44m. Minimum of Algol (β Persei).
6. 17h. 40m. to 18h. 41m. Moon occults λ Geminorum (Mag. 3 6).
11. Predicted perihelion passage of Brooks's periodical comet (1889 V–1896 VI).
11–13. Epoch of Geminid Meteors (Radiant 108° + 33°).
14. 12h. Venus in conjunction with the Moon. Venus 0° 5′ S.
15. Venus. Illuminated portion of disc = 0·586.
16. 3h. 7m. to 6h. 26m. Transit of Jupiter's Sat. III.
20. 12h. Mars and Saturn in conjunction (Mars 0° 33′ S.).
22. 12h. Sun enters Capricornus. Winter commences
23. 7h. 17m. to 10h. 36m Transit of Jupiter's Sat. III.
,, 8h. 27m. Minimum of Algol (β Persei).
25. 6h. 0m. Jupiter in conjunction with the moon (Jupiter 2° 40′ S.).
26. 5h. 16m. Minimum of Algol (β Persei).
,, 23h. 0m. Neptune in opposition to the sun.
31. 12h. 50m. Near approach of moon to Aldebaran (α Tauri).
,, 18h. 0m. Mercury at greatest elongation (19° 30′ E.)

Determination of Standard Stellar Velocities.—In accordance with the cooperative scheme for regularly determining the velocities of certain standard stars, Profs. Frost and Adams have, during the past twelve months, made independent observations of the radial velocities of thirteen stars, the results of which are given herewith:—

Star	Mean velocity in kilometres per sec.
α Arietis	−13·7
α Persei	− 2·1
β Leporis	−12·4
β Geminorum	+ 3·4
α Crateris	+47·4
α Böotis	− 4·8
θ Ophiuchi	−11·1
γ Aquilæ	− 1·8
γ Cephei	−41·2
ϵ Pegasi	+ 6·2
γ Piscium	−10·9
ι Aurigæ	+19·0
ϵ Leonis	+ 5 5

The Bruce spectrograph of the Yerkes Observatory, with various cameras attached, has been used, and, in the majority of cases, the spark spectrum of titanium has been employed to give the standard comparison wave-lengths. Three photographs of each star have been obtained, except in the case of β Leporis, where the low altitude and poor observing conditions have prevented more than one being taken. A range of 1·8 km. in the determined velocities of ϵ Leonis indicates the existence of a real variation, but more photographs must be measured before the point can be decided. An unaccountable difference of −0·5 km. is shown between the velocity of Arcturus as determined from eight earlier plates and that obtained from the five plates recently obtained, unaccountable because in the spectrum of this star the lines are so well defined (*Astrophysical Journal*, vol. xviii., No. 4).

New Elements for η Aquilæ.—From 352 observations of the magnitude of η Aquilæ, made at the Lyons Observatory between June 3, 1898, and December 22, 1902, M. M. Luizet obtained the times of fifty-five maxima and fifty-three minima, and, on comparing them with those calculated from the elements obtained by Schür, and published in "Chandler's Third Catalogue," he found that a difference amounting, in the mean, to +0·2 day existed, and therefore thought it advisable to compute a new set of elements. This he did by employing the maxima and minima data used by Schür, and combining with them the results obtained from his own observations; the result showed that it was necessary to apply a correction of 0·106 ± 0·021 day to the original epoch of maxima, and 0·0166 ± 0·035 day to that of minima, and, in each case, a slight correction to the length of the period.

Applying these corrections to the data used by Schür, one obtains for the original epochs

Maxima 2396168·738 days,
Minima 2396166·365 days,

and for the length of the period

7·176382 days.

The new elements, based on these data, are as follows :—

$$\begin{array}{ll} \text{Maximum} = \text{J.D. } 2396 \;\; 168{\cdot}738 \\ \text{Minimum} = \text{J.D.} \qquad\;\; 166{\cdot}365 \end{array}\Bigg\} \begin{array}{l} (\text{M.T. Paris}) + 7{\cdot}176382 \text{ E.} \\ + 0{\cdot}14 \sin (0^{\circ}{\cdot}044 \text{ E.} + 304^{\circ}) \end{array}$$

or

$$\begin{array}{ll} & \text{d. h. m. s.} \\ \text{Maximum } 1848 \text{ May} & 20\ 17\ 42\ 43 \\ \text{Minimum} \quad ,, \quad ,, & 18\ \ 8\ 45\ 36 \end{array}\Bigg\} \begin{array}{l} \text{d. h. m. s.} \\ + 7\ 4\ 13\ 59{\cdot}4 \text{ E.} \\ + 202\text{m.} \sin (0^{\circ}{\cdot}044 \text{ E.} + 304^{\circ}) \end{array}$$

and a comparison of the weighted means of his own and other observations leads M. Luizet to the conclusion that the interval between the principal and secondary maxima is 2·373 days, or 2d. 8h. 58m. (*Astronomische Nachrichten*, No. 3911).

ABSORPTION OF STAR LIGHT BY COMET 1903 *c*.—Prof. Max Wolf publishes, in No. 3914 of the *Astronomische Nachrichten*, two photographs of comet 1903 *c* taken on July 25 when the comet was passing in front of the 6·5 magnitude star B.D.+63°.1056. On comparing these photographs with the observations of comet 1902 III., Prof. Wolf arrives at the conclusion that the later comet exhibited a selective absorption of star light which was not exhibited by the earlier one.

PUBLICATIONS OF THE PULKOWA OBSERVATORY.—Vol. x. (2nd series) of the *Publications* de l'Observatoire Central Nicolas, edited by M. M. Nyrén, contains the details of the observations made with the prime-vertical transit instrument from 1869 to 1896. In the introduction, M. Nyrén discusses very minutely the errors of the instrument and their corrections, paying particular attention to the causes which might produce a small yet persistent residual as yet unaccounted for.

The results were analysed in order to test the validity of Chandler's "$\Delta\phi$" term for the variation of latitude, and they indicate that that observer's empirical formula requires some slight modification, although M. Nyrén hesitates to make a definite statement on this point. The constant of aberration as deduced from these observations is 20″·4423 if Chandler's term be considered; without the latter the value is 20″·4451, and M. Nyrén observes that, in the mean, this term seems of small importance.

In vol. xiii. of the same *Publications* M. Nyrén publishes a new catalogue of 1336 reference stars situated between dec. −30° and dec. +90°. This differs from Struve's Pulkowa catalogue in only containing stars between magnitudes 5 and 7; at least this was the original proposal, but it has been found necessary in practice to admit others which are just outside these limits. The idea of this selection was to include stars which were faint enough to give exact readings, and not too faint to be observed with the vertical circle used. Another feature of the catalogue is the division of the zone into squares, of which each side is 5° in length, and the observation of only one star in each zone, thus ensuring the even distribution of the reference positions without incurring too great a labour in the observations. The section of the zone −15° to +90° was observed at Pulkowa, and stars selected from the Bonn Durchmusterung were used, whilst the remaining section was observed at the subsidiary observatory at Odessa, where the Cordoba catalogue was used. Details of each observation made are given in the catalogue, and, together with the results, they occupy 487 quarto pages.

GUIDE FOR ASTRONOMICAL AND GEODETICAL CALCULATIONS.—Part ii. of Signor J. Boccardi's "Guide du Calculateur" will be found to be an extremely useful reference book by all who desire to perform calculations of observational results in astronomy or geodesy. It gives lucid explanations of many typical computations, such as the calculation of precessional effects, reductions to apparent place, elements of orbits, the determination of an orbit from three observations, and the special perturbations of an orbit; it also explains and illustrates the method of "least squares." Under the heading of "Geodesy" the solutions of many typical problems are explained and examples worked out, several special methods being named and clearly elucidated. Numerous worked examples are given throughout the book, each problem and method being clearly illustrated in this manner. The work is published by M. A. Hermann, 6 Rue de la Sorbonne, Paris.

THE EDISON ACCUMULATOR.[1]

MR. W. HIBBERT read a most interesting paper on the Edison accumulator before the Institution of Electrical Engineers last week. Since the first announcement of Mr. Edison's invention nearly three years ago, very little of an authoritative nature has been published about the cell; the paper which Dr. Kennelly read in May, 1901, showed that the invention was full of promise, and further results of more extensive experiments and of practical trials have since been awaited with eagerness. A description of the cell itself was published in NATURE in July, 1901 (vol. lxiv. p. 241), and as it has undergone little alteration since then we need not describe it in detail here; the active materials, it will be remembered, are nickel oxide and iron, and the electrolyte is a 20 per cent. solution of caustic potash; the chemical changes on charge and discharge may be represented by the equation

$$\overset{\text{After charge}}{NiO_2 | KHOaq | Fe} \rightleftarrows \overset{\text{After discharge}}{NiO | KHO.aq | FeO,}$$

the electrolyte serving merely as an oxygen carrier, and not taking any actual part in the final changes of the active material, as does the sulphuric acid in the lead-lead-peroxide cell. The active materials are packed in perforated steel pockets, and the plates, though thin, are rigid and light. The construction is thoroughly mechanical throughout, and the lightness is obtained without any sacrifice of durability,

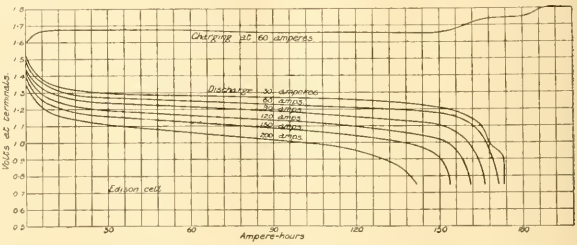

FIG. 1.—Discharge Curves of Edison Cell. From the *Journal* of the Institution of Electrical Engineers.

which is one of the chief faults of the lighter types of lead cells. The standard size of automobile cell is 13 inches high (over all) and 5·1×3·5 inches horizontally. The weight is 17·8 lb. The E.M.F. is approximately 1·35 volts, and the internal resistance 0·0013 ohm; the output at 60 amperes discharge is 210 watt-hours, the capacity working out, therefore, at 11·8 watt-hours per lb. This figure agrees very closely with those which were published originally; Dr. Kennelly put the output at about 14 watt-hours per lb., and, in the article referred to above, we calculated from a discharge curve which had been published an output of 10 watt-hours per lb. The lightest lead cells in some instances approach, or even exceed, these figures, but on the average the result is considerably better than that obtainable in practice with lead accumulators. It will be seen, however, that in many other respects the Edison cell promises to prove much superior, especially for motor-car work.

Mr. Hibbert's tests were made partly under laboratory conditions and partly on the road. The discharge curves reproduced in Fig. 1 were taken in the laboratory, and show that the Edison cell possesses in a remarkable degree one very desirable characteristic, namely, that of giving a good output in ampere-hours when discharged at heavy discharge rates. Taking the normal discharge current as 30 or 40

[1] "The Edison Accumulator for Automobiles." By W. Hibbert, Abstract of paper read before the Institution of Electrical Engineers. November 26.

amperes, the curves show that more than 80 per cent. of the normal ampere-hours can be obtained when discharging at so high a current even as 200 amperes. A lead cell under similar conditions would probably not give more than 50 per cent. of its normal output. Experiments on the road showed that this result could be obtained under practical conditions. A 32 mile run was made from Leicester to Northampton against a head wind all the way; on the level the current varied from 55 to 60 amperes, as against the usual 40; uphill it was from 90 to 100 amperes, and on one occasion rose above 150 amperes. The total discharge came out as 190 ampere-hours, the normal standing discharge being 160 ampere-hours. The battery had been fully charged before the start, 242 ampere-hours having been put in in 1 hour and 20 minutes. This particular case shows that there is an extra discharge—30 ampere-hours in this instance—which can be got from the cell; it is due to the fact that the voltage at the end of the discharge does not continue to drop rapidly as shown in the curves in Fig. 1, but, when it has fallen to about half a volt, becomes steady again for another hour. There is, in consequence, a reserve of capacity which, though not generally used, may prove very valuable in emergencies such as the above.

Some other results obtained by Mr. Hibbert may be quoted. A cell after being short circuited for 48 hours recovered its original capacity after two charges, and was apparently none the worse for this severe treatment. Experiments on the rate of charging were tried, and showed that high charging currents can be safely used. A fully discharged cell was recharged for an hour at 177 amperes; 124 ampere-hours, or 70 per cent. of the charge, were obtained on discharge at 60 amperes. Experiments on the road confirmed this result, 70 per cent. of the charge being obtained after charging at 200 amperes. The efficiency of the cell is not quite so good as that of a lead cell; the following figures were obtained under different conditions:—at 30 amperes charge and discharge 66 per cent., at 60 amperes 60 per cent., at 100 amperes charge and 60 amperes discharge 56 per cent., and at 177 amperes charge and 60 amperes discharge about 50 per cent. On the other hand, the cell endures a period of rest before discharge well, and also does not suffer if allowed to stand discharged for some time. If discharged immediately after charge a somewhat large discharge is obtained, but after two days' rest a discharge of 155 ampere hours is given; a further twenty-four days' rest only had the effect of diminishing the discharge to 125 ampere hours, or 80 per cent. of the discharge after the two days' rest.

The trials on the road were made in a runabout with a battery of 38 cells, weighing about 700 lb.; the total weight, with two persons, was about 2000 lb. The trials were planned to afford answers to the following questions:—

(1) Is the capacity the same on the road as in the laboratory?

(2) Will the battery stand excessive discharges on the road?

(3) Will it take a rapid charge and utilise it on the road?

(4) Will it recover after lying discharged for some time?

(5) Does the capacity fall off by reason of the shaking?

(6) What attention is required?

The experiments which we have already quoted show that the answer to the first four questions is in the affirmative. With regard to the fifth question, the results were very satisfactory. The car had run 400 miles before Mr. Hibbert took it over; its capacity was then 159 ampere-hours on standing discharge. Mr. Hibbert ran it in all 500 miles in the course of a month, and at the end of that time the capacity on standing discharge was 158 ampere-hours, showing, therefore, no appreciable deterioration. As regards attention, Mr. Hibbert found very little to be required; none of the terminals worked loose or showed signs of getting unduly warm with the heavy charging currents sometimes used. The only matter that had to be attended to was the replenishing with distilled water which was required after every five or six charges.

The general results of Mr. Hibbert's tests are most encouraging; the only point on which further information is required is durability, but all the evidence is in favour of this proving satisfactory. It certainly seems as if the hopes aroused by Dr. Kennelly's paper are within measurable distance of realisation.

M. S.

THE UNITED STATES GEOLOGICAL SURVEY.

We have received parts i. to iv. of the twenty-second annual report of this survey for 1900–1. In part i., after the administrative report by Mr. C. D. Walcott, the director, there is an elaborate essay on the asphalt and bituminous rock deposits of the United States. The author, Mr. G. H. Eldridge, points out that while sandstones are storage reservoirs for mineral oils or bituminous deposits, limestones may be the place of origin as well as the means of storage. Ozocerite has been formed in some strata by the draining of petroleum pools or of strata richly saturated in oil. The author instances a reservoir in California that rests on granite, and has been filled from overlying deposits.

In part ii. ore deposits are dealt with. There is an account of the tungsten mine at Trumbull, Conn., and it is mentioned that wolframite is produced by alteration of scheelite through replacement of its calcium by iron and manganese. The ore deposits of Rico Mountains comprise galena, often argentiferous, sphalerite or zinc blende, chalcopyrite and magnetite; those of the Elkhorn district include argentiferous galena and gold, and the metalliferous deposits are believed to have been derived from igneous rocks (gabbro) lying beneath limestones, through the agency of uprising hot siliceous waters. The Blue Mountains of eastern Oregon comprise, near Baker City, an important gold-field. The mountains consist of cores of older rocks with Tertiary rhyolites, andesites, and basalts. Gold and silver occur in veins in the older rocks, and gold occurs also in placer deposits. In Monte Cristo, Washington, there are ores of copper, lead, zinc and arsenic. The lead and zinc mines of the Ozark region are dealt with in considerable detail, with respect to the relation and to the concentration of the ores, whether by ascending or descending waters. The original precipitation of the metals is traced back to the agency of organic matter, aided by concentration and evaporation in shallow seas, such as characterised the dolomitic beds of Cambro-Silurian age. Analyses show minute, but important, amounts of zinc and lead in the pre-Cambrian, Cambro-Silurian and Carboniferous rocks. The workable ores have been deposited in the fractured and brecciated areas of Carboniferous Limestone. The author discusses the chemical processes which have led to the deposition of these ores; these have in succession been oxidation of sulphides, transportation as sulphates, and precipitation in the crevices of the rocks as sulphides. Some of the ores have since been superficially changed to carbonates.

Part iii. deals with coal, oil and cement. There are statistics relating to the coal-fields of the United States, particulars about the anthracite coal-field of Pennsylvania, with its disturbed, vertical and overturned coal, and descriptions of various other coal-fields, and of the Gaines oil-field of Pennsylvania. Accounts are given of the Portland cement industry in Michigan, and of the manufacture of hydraulic cement in south-west Arkansas, where chalk comparable with that of England is used.

Part iv. deals with hydrography, with stream measurements, the hydrography of the American isthmus, and of the high plains.

We have received also part i. of the twenty-third annual report for 1901–2. It contains the report of the director, Mr. C. D. Walcott, who describes the methods of work, and appends a memoir, with portrait, of the late Clarence King.

In addition we have received a preliminary report on the Ketchikan mining district of Alaska, by Mr. Alfred H. Brooks, who deals with the gold-bearing properties and with certain silver and lead deposits; and a reconnaissance of the north-western portion of Seward Peninsula, in Alaska, by Mr. A. J. Collier, with reference to the more important gold-fields. These reports, which are naturally somewhat sketchy, will be of service to those who contemplate mining enterprises in the districts.

Two monographs of the Geological Survey have recently been published. Monograph No. xlii. is on "The Carboniferous Ammonoids of America," by Mr. James Perrin Smith. The writer tells us that he makes "no distinction between goniatites and ammonites, because there is none that will hold." He remarks that while nearly all the characteristic

European genera are present in America, some are extremely rare, represented by a single species; others have a different range in America from that in Europe. These differences of range and association give hints as to the region where some of the forms originated, but the information is too indefinite to allow any positive statements as to the faunal geography of that time. The author, however, concludes that at least periodically there was easy intermigration between the American and the European waters, for the community of genera, and even of species, is too great to be explained by any other hypothesis. We note that *Glyphioceras calyx, Goniatites crenistria, G. sphaericus* and *G. striatus* are recorded from the Lower Carboniferous of America. The work is illustrated by twenty-nine plates.

Monograph No. xliii. is on "The Mesabi Iron-bearing District of Minnesota," by Mr. Charles K. Leith. The iron-bearing formation occurs in the Upper Huronian, and in what is known as the Biwabik division. This comprises a variety of rocks, including slates, cherts, and "greenalite." This last-named substance consists largely of minute granules of green ferrous silicate, without potash, and is named greenalite for convenience. The cherts and iron ores are shown to develop mainly from the alteration of the greenalite granules. Interbedded slate-rocks occur, and paint-rocks have resulted from their alteration. The iron ores are in basin-shaped deposits of considerable horizontal extension. Full particulars are given of these and of the methods of mining, while other rocks which enter into the structure of the district, the Archæan, Lower Huronian, the Keweenawan gabbro, the Cretaceous rocks, and Glacial drifts are described. The work is accompanied by maps, pictorial views, and plates of microscopic sections.

A series of *Bulletins* of the Geological Survey (published 1902–3) has been received. No. 203 comprises the invaluable "Bibliography and Index of North American Geology for 1901," by Mr. F. B. Weeks; 866 works are listed, and they are for the most part accompanied by brief notes of the contents. In No. 191, also the work of Mr. Weeks, there is a list and references to "North American Geologic Formation Names," a work of unquestioned utility. We cannot help thinking that formational terms should, wherever possible, be derived from original place names. Even names like the Appotomax, Bearwallow, Caloosahatchie, Shawangunk or Wapsipinicon beds are preferable to those of Alnwick, Barnstaple, Falmouth, Tisbury and Tiverton beds, some of which have a meaning in this country. Other native names, such as the Anamosa, Keewatin, Shenandoah and Wyoming, and even the Mormon beds, are appropriate.

No. 206 is a study of the fauna of the Hamilton (Devonian) formation of the Cayuga Lake section in Central New York, by Mr. H. F. Cleland. An attempt was made to collect the complete "faunule" from each zone, and it is stated that the examination failed (with one possible exception) to reveal any evolutional changes. The species are as distinct or as variable in one portion of the section as in another. Apparently it makes little difference how much time elapses so long as the conditions of environment remain unchanged. Some repetition of faunas is noted.

In No. 205 Mr. G. B. Shattuck deals with the Mollusca of the Buda (Cretaceous) Limestone, and Mr. T. W. Vaughan deals with the corals. The work is accompanied by many plates of fossils. In No. 204 the fossil flora of the John Day Basin, Oregon, is described and illustrated by Mr. F. H. Knowlton. The beds which yield the plants are Eocene and Miocene.

In No. 195 Mr. T. N. Dale contributes a second paper on structural details in the Green Mountain region and in eastern New York. Various structures in pre-Cambrian and Cambrian rocks, showing the complex interaction of mechanical and chemical processes, are described, and in one case the amount of shear is indicated by deflected annelid borings.

Economic geology receives treatment in several *Bulletins*. No. 199, by Mr. I. C. Russell, is on the geology and water resources of the Snake River plains of Idaho. Many curious volcanic features are illustrated, including some volcanic bombs. No. 198 is on oil sand in Ohio; No. 200, on borax deposits in California, and No. 202 on gold and silver in western Kansas. In No. 207 there is an essay on the action of ammonium chloride upon silicates.

Geography is illustrated in No. 196, wherein Mr. J. S. Diller treats of the topographic development of the Klamath Mountains in California and Oregon; in No. 197, by Mr. H. Gannett, on the origin of some ten thousand place names in the United States; and in No. 201, which contains results of primary triangulation.

The Maryland Geological Survey, under the direction of Prof. W. B. Clark, sends two memoirs on the counties of Cecil and Garrett. These deal exhaustively with the local geology and topography, with the rocks igneous and stratified, the mineral resources, soils, climate, forests, &c. They are well illustrated and admirably printed, and with their colour-printed maps they may be regarded as in all respects models of what geological survey memoirs should be.

H. B. W.

WINTER WHITENING OF ANIMALS.[1]

THE winter whitening of animals, though of intense interest to zoologists, is very imperfectly understood. Most writers are satisfied to believe that this colour change was perfected somehow under the action of natural selection for the protective purposes of adaptation to environment. Its origin they leave as an unsolved problem.

I find, however, that the change has a deep physiological significance. There is, for instance, in mammals a definite sequence in which the various parts of the body whiten. This sequence corresponds to the summer accumulation of fat in the panniculus adiposus. Thus the belly, where peripheral fat is thickest, is permanently white, and the rump, where also fat accumulates thickly, is usually the first part to whiten in winter.

Many northern mammals and birds not usually regarded as of the winter-whitening category are lighter in winter than in summer. The whiteness or white patches assumed in the former season correspond to the fat tracts, so that these species may be regarded as subject to the same process.

In the northern summer most animals accumulate fat, always in a definite manner as regards the regions where it is deposited. This fat is indicative of deficient oxydisation and of sluggish metabolism, and the process of its accumulation is therefore one of atrophy. The fat accumulation and atrophy are most marked in autumn, at which season metabolism is therefore lowest. With the onset of winter cold, the atrophy may extend to the hairs. Their pigment (as observed by Metchnikoff) is then removed, always, however, commencing with those parts where peripheral fat is thickest, and atrophy therefore greatest. Should there be a change of coat at this time, the new hairs are influenced by the same conditions. In very cold countries they come up white all over the animal; in more temperate regions the parts only where fat is thickest are white.

Although a pigmented hair can thus undergo atrophy and loss of pigment, I know of no case where the colour is replaced. Animals once whitened remain so until the spring moult.

These facts apply broadly to birds and mammals, but the hare and stoat are the species which I have studied especially.

Similar laws govern a great deal of the distribution of the white colour throughout the vertebrate phylum, wherein the connection between white colour and the peripheral fat tracts (thus indicating local atrophy) may be widely traced. Thus domestic animals, nearly all of which are prized most for their power of accumulating fat, exhibit a strong tendency to the development of white patches. In both these and in wild animals the belly, where occurs the principal fat tract, is the most frequently white part; next follow the rump, and parts of the neck, of the limbs and of the head.

Marked exceptions are, no doubt, frequently due to unusual arrangements of the panniculus adiposus. Thus in the badger, a representative of a family in which the back is usually whiter than the belly, I find a correspondingly exceptional arrangement of the fat tracts.

[1] Abstract of a paper read before the Royal Irish Academy on May 11 by Capt. Barrett Hamilton, on a physiological theory to explain the winter whitening of birds and mammals living in snowy countries, and the most striking points in the distribution of white in vertebrates generally.

The white of the head—the "blaze" of horses, the facial stripes of the badger—often affects regions not of fat accumulation, but where the skin immediately overlies bone and membrane (frontals and nasals and zygomatic arch), which thus seem to produce an atrophy similar to that caused by underlying fat.

In many animals the hair-atrophy assumes the form not of whitening, but of baldness. Marine mammals are hairless in proportion to the development of their peripheral fat-layer; fattening cattle lose their hair, while the baldness of man corresponds in position to the "blaze" of horses, and the bare buttocks of monkeys to the white rumps of other animals.

Yellow and red frequently follow the same rules of distribution as white. They are well known to be fat pigments.

I must carefully guard myself against the extension of my theory to all cases where white occurs in vertebrates. It is obvious that not all animals are subject to this atrophy, and that there must be other causes for absence of pigment. It seems highly probable from what I have written that the known unevenness of animal coloration is but the external indication of uneven nutrition in different regions of the body.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Prof. J. A. Ewing, F.R.S., and Prof. Karl Pearson, F.R.S., have been elected honorary fellows of King's College.

Mr. W. Chawner, Master of Emmanuel, has been appointed an elector to the Sadlerian professorship of mathematics, in succession to the late Dr. N. M. Ferrers.

Mr. C. H. Talbot has presented to the university a number of instruments used for the researches of his father, Mr. H. Fox Talbot, F.R.S.

The Duke of Bedford has presented to the Museum of Zoology a number of valuable specimens of *Cervus davidianas*.

Mr. W. Bateson, F.R.S., and Mr. A. C. Seward, F.R.S., have been appointed members of the botanic garden syndicate; Prof. Marsh a member of the museums syndicate; Mr. W. M. Coates and Mr. E. T. Whittaker members of the observatory syndicate; Dr. D. MacAlister and Prof. Marsh members of the State medicine syndicate; Dr. J. Griffiths a member of the medical board; Mr. F. H. Neville, F.R.S., a member of the board for physics and chemistry; Mr. J. E. Marr, F.R.S., a member of the board for biology and geology; Mr. A. C. Seward, F.R.S., a member of the board for agricultural studies; Mr. F. C. Parsons an examiner in human anatomy.

The grace for the appointment of a syndicate to consider changes in the university studies and examinations was carried by 170 votes *placet* against 79 *non-placet*. The members of the syndicate as proposed were appointed by 156 votes to 92.

IT is reported that the late Mr. Seale Hayne has left residue estate amounting to more than 100,000*l*. for the purpose of establishing a college of science, art, and literature in Devonshire.

UNDER the auspices of several Greek educational societies recognised by the State, an educational congress will be held in April, 1904, in Athens. In connection with the congress it is intended to organise an exhibition of educational books and apparatus which will include an international section. Foreign contributors should deliver their exhibits in Athens not later than February 14, 1904. Detailed information can be obtained from the secretary, M. G. Drossinis, Comité d'Organisation du Congrès hellénique d'Éducation, Bureaux du Syllogue pour la Propagation de Livres utiles, 42 Rue de l'Académie, Athens.

A COMMUNICATION from the Privy Council has been received by the agents for the promotion of the proposed University of Yorkshire with reference to the application for a charter for the Yorkshire College at Leeds. The Lords of the Committee of Council state that, in view of the additional information as to their financial position and prospects which the promoters of the Yorkshire College petition are able to furnish, they agree to recommend the grant of a charter following generally the terms of the draft submitted, on the understanding that the West Riding County Council makes a substantial subvention towards the maintenance of the university, and that the promoters undertake to raise a capital sum of at least 100,000*l*. by the earliest possible date. As to the title of the university, it is pointed out that "The Victoria University of Yorkshire" implies a possessory interest in the whole of Yorkshire, and objection might be made to it. Also, the use of the name "Victoria" might cause confusion with the "Victoria University of Manchester."

THE report on the work of the department of technology of the City and Guilds of London Institute for the session 1902–3 shows a marked increase in the number of examinees from India and the colonies. Last year India sent up 29 candidates and the colonies 148. This year 53 Indian and 238 colonial candidates were presented for examination, 51 from New South Wales and 167 from New Zealand. Applications have been received from Cape Colony for the holding of examinations in telegraphy and telephony, manual training and other subjects, and the Agent-General has undertaken to transmit the question papers to the colonial educational authorities and to afford all necessary facilities for the conduct of the examinations. The number of candidates in cotton spinning examined in India is steadily increasing. In mechanical engineering there is also a large increase. There has been also a continuous and uninterrupted increase in the total number of classes registered by the Institute for instruction and in the number of students in attendance. While in 1902 the number of centres was 364 with 2320 classes and 36,189 students in attendance, in 1903 there were 396 centres, 2789 classes, and 38,638 students.

AT the annual dinner of the Institution of Mining and Metallurgy last week, Sir W. Anson, Parliamentary Secretary to the Board of Education, in proposing the toast of "The Institution," referred to the scheme for a great school of technology in London, and promised the cordial and hearty cooperation of the Board of Education. Some months ago, he continued, the Board had in view the appointment of a committee to inquire into the Royal College of Science and Royal School of Mines in their special relation to this scheme. He thought he could safely say that that committee, of which Sir F. Mowatt had consented to become the chairman, would be appointed, and would commence work in January next. He was glad to be able to assure them of the cordial cooperation of the Board of Education in any scheme for the advancement of practical scientific education. He welcomed the efforts of the Institution of Mining and Metallurgy to advance technological study, because it was of immense importance to the education of the country that they should find among men of business this appreciation of the value of knowledge, of training, and of study.

BY the will of the late Mr. Gordon McKay, inventor of the sewing machine that bears his name, Harvard University receives a very large bequest for applied science, estimated to be about 800,000*l*., and eventually much more. We learn from *Science* that according to the terms of the will, Harvard University is to receive 200,000*l*. when this amount has accumulated from the income, and is thereafter to receive 80 per cent. of the balance of the income after annuities have been paid, and is to receive the entire residue of the estate after the death of the last surviving annuitant. The portion of the will defining the object of the bequest is as follows:—The net income of said endowment shall be used to promote applied science. First, by maintaining professorships, workshops, laboratories and collections for any or all of those scientific subjects which have, or may hereafter have, applications useful to man; and, second, by aiding meritorious and needy students in pursuing those subjects, especially in connection with mechanical engineering. *Science* also states that under the will of Sarah B. Harrison, Yale University is given 20,000*l*. in memory of her brother, the late Gov. Henry B. Harrison, of Connecticut, who for thirteen years was a member of the Yale Corporation. The money is given in trust, the income to be used for such purposes as the university shall desire.

A BILL to carry out the recommendations of the Universities Commission, those recommendations having been accepted by the Government of India after consultation with the local administrations, was introduced by the Hon. Mr. Raleigh on November 4 to the Supreme Legislative Council of India. We learn from the *Times* that the Bill reduces the number of ordinary fellows to 100 in the case of the senior universities, and to 75 in the cases of the Allahabad and Punjab Universities. The "syndicate" is also to be reduced in membership, so as to make it a compact working body, to be recognised as the executive authority of the university entrusted with certain powers independently of the Senate. The existing members of the Senate will be continued merely as honorary fellows, and be divested of any share in the active business of the university, excepting the right to vote for legislative or municipal representatives. The privilege of electing fellows will be maintained in cases where it exists. It will be for the Government to decide as to the extension or withdrawal of the affiliation of colleges, the function of the university in this respect being merely advisory. Sir Denzil Ibbetson announced that, with the approval of the Secretary of State, it had been decided to make for five years special grants-in-aid to universities and colleges the claims of which to special assistance in carrying out the contemplated reforms are established.

DR. FREDERIC ROSE, His Majesty's Consul at Stuttgart, has made another report to the Foreign Office on technical instruction in Germany. This report is published as No. 600 in the miscellaneous series of diplomatic and consular reports, and is concerned with the building and engineering trades' schools, the aims, organisation and equipment of the Baugewerkschulen being described. Dr. Rose gives very instructive accounts of the schools of this kind in Stuttgart, Karlsruhe, and Nuremberg, and concludes with a history of the development of similar technical institutions in Prussia. These building and engineering trades' schools play an important part in German technical education, being intended, not to train captains of industry, but rather subaltern officers and the rank and file of the industrial army. The schools are in some cases State schools, in others municipal schools. In Prussia nineteen out of twenty-two existing are State schools. The instruction is given both in winter and summer in some schools, in others during the winter months only. It varies to a certain extent at the various schools, both as regards duration and extent. For example, Prussian schools possess four classes of half a year each for building, whilst Nuremberg possesses five, and Stuttgart and Karlsruhe six classes for the same purpose. As illustrative of the aims of these schools, reference may be made to that at Stuttgart, where in the building departments instruction suitable for the following workers is given:—practical master builders, subordinate building officials, road and street inspectors, fire prevention inspectors, railway inspectors, and hydraulic engineering *techniker*; in the mechanical engineering department to managers of workshops and factories, overseers, machine draughtsmen, &c.; and in the surveying department to public surveyors and drainage and irrigation supervisors.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 19.—"On the Rapidity of the Nervous Impulse in Tall and Short Individuals." By Dr. N. H. **Alcock**. Communicated by A. D. Waller, M.D., F.R.S.

While the effect of varying conditions on the rapidity of transmission of the nervous impulse has been fully studied, no research has yet been made as to whether the stature of the individual and the corresponding difference in the lengths of homologous nerves have or have not any influence on this rapidity, and as recent work has rendered it desirable that the question should be considered, the research here recorded was undertaken to this end.

Two series of observations were made:—(1) On the frog; (2) on man.

The results lead to the following conclusions:—

(1) The rapidity of the nervous impulse *per unit length* is the same whatever be the stature of the individual.

(2) The time taken by this impulse to travel from the centre to the periphery is greater in taller individuals.

(3) The nodes of Ranvier exercise no influence on the rate of impulse.

Physical Society, November 27.—Dr. R. T. Glazebrook, F.R.S., president, in the chair.—Mr. Horace **Darwin** exhibited an electric thermostat. The thermostat shown at the meeting was made for Lord Berkeley, and is similar to one made for the spectrograph of the 24-inch refractor of the Royal Observatory, Cape of Good Hope. The vessel the temperature of which is to be maintained constant is surrounded by oil contained in a bath. In the oil are placed two heating-coils, through which electric currents pass. By automatically controlling these currents the temperature of the oil, and consequently of the inner vessel, is kept very nearly constant. The control is effected by means of a Wheatstone-bridge in the outer oil-bath. This bridge has two opposite arms of copper and two of manganin, so that it is only balanced at some definite temperature. Its deviations from balance affect the position of a long horizontal boom attached to the suspended coil of a galvanometer. The position of the boom determines the greater or less descent of a "hit or miss" arm which is periodically raised by a rotating-cam, and can only fall to its lowest position when the galvanometer-boom is to one side and allows it to pass; this position of the boom corresponds to a fall of temperature of the controlling-bridge. Thus the position of the "hit or miss" arm at its lowest position depends on the temperature, and it is the variation of this position which regulates the amount of current passing through the heating-coils. The thermostat supplied to the Cape Observatory is capable of keeping the temperature within 1/100° C. for a period of eight hours.—On the occurrence of cavitation in lubrication, by Mr. S. **Skinner**. The experiments described in the paper arose from an observation made when determining the refractive index of a liquid by means of Newton's rings. As Newton showed, the rings can be obtained when a liquid is run into the space between the lenses. If when the liquid has been introduced the upper lens be rolled on the lower, the observer sees following the central dark spot a crescent-shaped space, very bright provided the illumination be sufficiently oblique. This is a vacuous or vapour-filled space, for when the motion of rolling ceases the liquid flows into the space and completely fills it. The inflow of the liquid depends in some way on the viscosity, and the effects are more pronounced when a more viscous liquid is used. The most convenient mode of observation is to use a deeply-coloured liquid, and to look at the space by transmitted light. The author has found that a convenient liquid is a strong solution of fuchsin in glycerin. The cavities which are formed must be produced either by splitting the liquid itself or by tearing the liquid from the glass surface. The effect may be described as a case of "cavitation." Some experiments were made to imitate the actual case of a fully lubricated axle rotating under a bearing. In ball-bearings completely immersed in oil, the experiments show that there must be a small cavity near the point of nearest approach of each ball to its neighbours, and also to the surface on which it is running. As the friction of the bearing is the viscous friction of the oil, it follows that the friction must be considerably reduced by the formation of these cavities, which are filled with relatively non-viscous vapour. The high lubricating property of oils owes its origin not only to their superior viscosity, but also, possibly, to the facility with which cavities may be formed in them.—Prof. R. **Threlfall** exhibited and described the following instruments which he has used in the testing of electric generators by air calorimetry:—(1) A "hot-wire voltmeter" accurate to 1/100 volt. The wire in this instrument is very fine, and special precautions are taken to keep the tension on it constant, so that the elongation measured is due only to the expansion of the wire caused by the heating effect of the current. (2) A "Pitot tube" for the measurement of air velocity, the velocity being proportional to the square root of the pressure produced in the tube. (3) A "manometer" for determining pressure differences in Pitot tubes with accuracy. This consists essentially of two bottles containing coloured water, which are connected by a syphon, and the air-space of each bottle is put in communication with

its appropriate tube. The readings are taken by setting a pair of needle-points just to touch the liquid surface, and then measuring how they differ in level by micrometer screws, or by callipering suitable jaws. The instrument is trustworthy to 0·01 mm. of water-pressure. (4) A multiplying pressure-gauge in which the motion of a float or ball is used to operate a finger moving round a dial. The dial is divided in such a manner that the square roots of the pressure-differences are read off. Air velocities are therefore given directly.

Geological Society, November 4.—Sir Archibald Geikie, F.R.S., vice-president, in the chair.—Metamorphism in the Loch-Lomond district, by Mr. E. Hubert **Cunningham-Craig**. The area dealt with includes all the Highland rocks on either side of the loch, as well as the area lying to the eastward. Each stage of the progressive metamorphism can be studied without confusing its effects with those of another process. The rocks from the Leny-Grit group and the Aberfoil-Slate group show dynamic metamorphism, and at Rudha Mor the beginning of the thermal type is seen. This is superseded by a constructive metamorphism, probably of hydrothermal type, and the rocks become more highly crystalline, until all clastic structures are obliterated. The segregation of like minerals into folia, the total recrystallisation, and the genesis of new mineral-groupings, result in the production of coarsely-crystalline albite-gneisses from siliceous and felspathic grits.—On a new cave on the eastern side of Gibraltar, by Mr. H. D. **Acland**. This cave is situated south of the eastern end of the tunnel, which pierces the Rock from the dockyard on the western side to "Monkeys' Quarry" on the eastern. The main hall is about 70 feet high and 45 feet wide, and has a smooth stalagmite floor resting on breccia, and a stalactitic roof covering the limestone of the Rock. Its floor falls to a point 19 feet above sea-level. The lower gallery descends at its far end to little short of sea-level. Its floor consists of stalagmite resting on calcareous sand; this on coarse sand, followed by rubbly and calcareous grit, which in time rests on the rock-floor at a depth of 15 feet. In the calcareous grit are well-rounded stones, some pierced by pholades. At a depth of 13 feet were echinids and barnacles. Two other galleries were explored, and in these the walls are pitted to a height of 28 feet above sea-level. The author concludes that the cave existed at first as a fissure, to which the sea obtained access for a long period, and during this period the rock was elevated some 42 feet. The cave was closed to the sea at a period geologically recent, and the breccia and sand-slopes date from a still more recent period.

Linnean Society, November 5.—Prof. S. H. Vines, F.R.S., president, in the chair.—Dr. W. G. **Ridewood** exhibited the frontal bones of a horse showing rudimentary horns. The bony protuberances were about three inches apart, and were set upon the curved ridges that constituted the anterior margins of the areas of origin of the temporal muscles. In the natural sloping position of the head in the living horse they would have been vertically above the orbits. Dr. Ridewood pointed out that the exceptional cases of horny bosses occurring in horses could hardly be regarded as instances of reversion, for the palæontological record of the evolution of the horse is remarkably complete, and no indications of horns are to be found in the extinct congeners of the modern equines.—Prof. **Weiss** exhibited some preparations and photographs of a mycorhiza or mycorhizome from the Coal-measures. The preparations were in part from the Cash collection at the Owens College, Manchester, and in part from Dr. Scott's private collection. They showed the existence in a small root-like organ of fungal filaments presenting all the appearances of those found in the roots of many orchids and in the rhizome of Psilotum.—Mr. B. H. **Bentley** exhibited a large series of lantern-slides, designed for teaching purposes, which he had taken, illustrating certain types of floral pollination, and bees and other insects in actual operation.—Mr. L. A. **Boodle** read a paper on the structure of leaves of the bracken, *Pteris aquilina*, in relation to environment. It is well known that in dry exposed situations the bracken produces leaves of a hard dwarf habit, while in very sheltered localities the leaves are quite soft. This difference in external characters is accompanied by a difference in structural characters. The exposed leaf has a hypoderm, and is a distinctly xerophytic "sun-leaf"; the other type of leaf is a pronounced "shade-leaf," having no hypoderm, and weakly developed palisade-tissue or no definite palisade. A similar difference may occur in different leaves of the same plant, or in different parts of the same leaf when shelter and exposure are sufficiently localised. A slightly xerophytic plant, when transferred to a greenhouse, produced shade-leaves only (though the illumination was fairly strong), and in these leaves the indusia were considerably reduced. The bracken is thus very plastic in its relation to environment.—A paper by Mr. E. P. **Stebbing**, on the life-history of a new Monophlebus from India, with a note on that of a Vedalia predaceous upon it; with remarks on the Monophlebinæ of the Indian region, was, in the absence of the author, read for him by Mr. G. S. Saunders. Up to 1901 only five species of the genus Monophlebus were known as Indian, and four of these were described from the male insect only; in that year the writer discovered both sexes of two new species, which had been named by Mr. E. Ernest Green, Government entomologist, Ceylon, *Monophlebus Stebbingi* and *M. Dalbergae*, whilst a third species, of which the females alone are known, was named *M. Tectonae*. These coccids infest forests in large numbers, and in consequence their ravages are serious. The amount of nutriment withdrawn from the trees is extraordinary, and the extruded sugary fluid may be heard falling like rain in an infested forest. The predaceous *Vedalia Guerinii*, Crotch, was then described, and its method of attack and great voracity; in turn, it is parasitised by a small fly whilst in the larval stage.

PARIS.

Academy of Sciences, November 25.—M. Albert Gaudry in the chair.—The relation between sun-spots and terrestrial magnetism. The utility of continual registration of the variable elements of the sun, by M. H. **Deslandres**. After a critical examination of the various hypotheses which have been put forward to connect solar phenomena with magnetic storms, the conclusion is arrived at that the solution of the problem has not yet been reached.—On the geological significance of anomalies in gravity, by M. **de Lapparent**. It is generally accepted that gravity is in excess of the average in oceanic regions, and is below the average on land. The suggestion is made, in opposition to the views of M. Faye, that the observed anomalies are due rather to the effect of dislocation than of the low temperature of the ocean floor.—On the reinforcement of the action of the bundle of light rays upon the eye, when accompanied by the *n*-rays, by M. R. **Blondlot**. It has been shown in previous papers that a feebly illuminated object increases in brightness when the *n*-rays are allowed to fall on it. It has now been found that if the *n*-rays are directed towards the eye instead of the object, a similar reinforcement is observed.—M. Émile Bertin was elected a member in the section of geography and navigation in the place of the late M. de Bussy.—On functional equations and the theory of divergent series, by M. L. **Fejer**.—On a system of three functions of real variables, by M. **Pompeiu**.—On the possibility of sustaining in the air an apparatus employing a helix, using an internal combustion motor, by M. Charles **Renard**. The reduction in the weight of an internal combustion motor per horse-power developed, now brought as low as 2·5 kilograms per horse-power, renders possible the use of a light helix in an aërostat. The theory is given for the conditions necessary in practice.—On the measurement of the effect of electric waves at a distance by means of the bolometer, by M. G. **Tissot**. The use of a bolometer as a detector has given readable results at a distance of 40 kilometres. The most advantageous arrangement of the apparatus has been worked out experimentally.—On the colour of aqueous solutions of methyl orange and the change produced by acids, by M. P. **Vaillant**. Simultaneous observations of electrical conductivity and molecular absorption (measured with the Gouy spectrophotometer) show that neither the theories of Ostwald nor of Küster are completely in accord with fact. The results point to a progressive molecular transformation of methyl orange under the action of acids, the change being more rapid with the stronger acids.—The modes of deformation and fracture of iron and mild steel, by MM. F. **Osmond**, Ch. **Frémont**, and G.

Cartaud.—Influence of the gases on the separation of metals by electrolysis: the separation of nickel and zinc, by MM. **Hollard** and **Bertiaux.** The introduction of a sulphite, preventing the evolution of oxygen at the anode, permits of the easy separation of nickel from zinc by electrolysis. Experimental analyses are given.—On oxalacetic acid, by M. L. J. **Simon.** The ether is treated with concentrated hydrochloric acid; the free acid, which is insoluble in this liquid, separates completely in about forty-eight hours.—The condensation of the salts of dinaphthopyryl with phenols, by M. R. **Fosse.**—The synthesis of nicotine, by M. Amé **Pictet.** Starting with nicotinic acid, this is converted into β-aminopyridine, the dry distillation of the mucate of this base giving a N-pyridyl-pyrrol. The vapours of this substance, passed through a red-hot tube, give α-pyridyl-pyrrol, which is methylated, giving the isodipyridine of Cahours and Étard (the nicotyrine of Blau). This gives inactive nicotine on suitable reduction, and from this an alkaloid identical in all respects with natural nicotine was obtained in the usual way with dextrorotatory tartaric acid.—The morphogenic action of water in motion on hydra, by Mme. S. **Motz-Kossowska.**—On the function of certain figured elements in *Sipunculus nudus*, by M. F. **Ladreyt.**—On the medusa of Victoria Nyanza, by M. Ch. **Gravier.**—On a double fusion of the membranes in the zygospore of Sporodinia, by M. Paul **Vuillemin.**—On a bacterial disease of the beetroot causing yellowing, by M. G. **Delacroix.** This disease attacks both the forage and sugar beet; practical suggestions are given with a view to its prevention.—On the formations of the zone of quartzites and conglomerates below the Devonian in the Northern Urals, by MM. L. **Duparc** and F. **Pearce.**—On the structure of the Hohe Tauern, in the Tyrolese Alps, by M. Pierre **Termier.**—Contribution to the study of the sodic rocks of East Africa, by M. H. **Arsandaux.**—The volcanic rocks of the island of Eubea, by M. **Deprat.**—The morphogenic action of crotaphytic muscles on the skull and brain of the Carnivora and Primates, by M. R. **Anthony.**—Comparison between the nervous effects of the Becquerel rays and those of light rays, by M. Georges **Bohn.** The action of radium rays upon the teguments is very complicated, acting upon the peripheral nervous filaments, producing a kind of anæsthesia.—On the existence in the animal organism of a diastase possessing simultaneously both oxidising and reducing actions, by MM. J. E. **Abelous** and J. **Aloy.**—On the marsh gas fermentation and the ferment which produces it, by M. **Mazé.** From a fermenting mass of dead leaves a specific organism has been isolated capable of producing methane during the fermentation of suitable solutions.—On tuberculins, by M. **Beraneck.**—A Crookes bulb for radiotherapy, by M. **Audin.** A description of an X-ray tube specially adapted for the treatment of cancer of the mouth and throat.

BUDDHISM IN INDIA.

Buddhist India. (Stories of the Nations Series.) By Prof. Rhys-Davids. Pp. xv + 332. (London: Fisher Unwin, 1903.) Price 5s.

THE keynote to Prof. Rhys-Davids's work on Buddhist India is to be found in his preface. He presents to us a picture of Indian social existence at the time when Buddhism first dawned on the world, avowedly depicted from the point of view of the Rajput rather than from that of the Brahmin. Nor is any apology needed for assuming this position. A history of England completed entirely from such references to its social and economic condition from time to time as might be found in the theological treatises of eminent churchmen would certainly not be regarded as satisfactory, and it is an immense gain to our power of realising past problems of Oriental life and civilisation that the learned professor should have been able to marshal so many points of valuable information from independent lay sources, and to give us new views from a new standpoint. He is at great pains to show the real position which the priesthood of India held in the seventh century A.D., when the world was ripe for Buddhism; and he deduces from an analysis of Pali writings (previous to the general adoption of Sanscrit as the classical language of literature) a very clear idea of early Brahminism in days when the alphabet, indeed, had long been introduced to India from Mesopotamia, but when "literature" existed in men's memories and not in the concrete form of manuscript. All this part of the book is excellent. We see the Kshatriyas—of the noble "colour" (not caste)—in their proper position of relative importance to the Brahmin, and the latter by no means enjoying that social status of dominant and arrogant priesthood which we have always been accustomed to regard as even more distinctive of early Brahminism than of the Brahminism of to-day.

The early Brahmin is now to be regarded as the thinker and learner, the philosopher and minister, ready to adapt his views to those of the public if necessary, with wide toleration seeking to preserve his influence by the adoption of elastic principles. His very gods changed with the times, and both free-thinking and free discussion were not only permitted, but encouraged to an extent probably unparalleled in the history of the world. The soul of the Upanishads had already become the one primeval world-soul from which all other souls emanated, when Buddhism arose; and the remarkable feature about this approximation to a great central truth was that it owed its existence, not to Brahmin philosophy, but to the conception of lay speculation. Thus Buddhism entered the world at the right psychological moment. The world of India at least was ready for it.

But deeply interesting as is this scholarly inquiry into the conditions of literature and religion which prevailed at the time of Buddha's birth, perhaps a little too much space in what is necessarily a crowded work has been devoted to it. It is true that we have graphic pictures presented to the imagination of village and town life, of social intercourse and the relations subsisting between the various grades of a society in which caste distinctions were real enough, but possibly not more pronounced than analogous distinctions in European countries at the same date; but they are restricted to Buddhist India, which was, after all, only a part of India, and we have very scanty glimpses of the relations existing between Buddhist India and the rest of the continent. Nor does the book much assist us to define the geographical boundaries of Buddhist India.

Buddhism was the paramount faith only at certain centres; these centres were far apart, necessitating long and weary pilgrimages from one to another. The earliest Buddhist records contain a "stock" list of the sixteen Powers which constituted Buddhist India, but this list is geographically deficient, for it ignores the whole of south India and Ceylon, and only deals with the area of northern India bounded by the Himalayas on the north, the Vindhyas on the south, the Ganges on the east, and the mountains beyond the Indus on the west. Undoubtedly the most remarkable feature about Buddhism is its absolute extinction in India, the land of its birth, at the hands of the Brahmins, and its extraordinary development in countries beyond India, where it is still a living and a proselytising faith. The connection between Buddhist India and the countries of the borderland, the gradual spread of the faith to the valley of the Kabul River and beyond Kabul to Bamian and Haibak; or to the Swat Valley and Dir, and over the Himalayas to the cities (now buried beneath the sand) of Khotan, would have been an interesting subject of inquiry, for it would illustrate the enormous influence of Buddhist India in the process of civilising the rest of Asia.

The apostles of Buddhism claim that it has been the greatest civilising agent in the world. It has left no mark in India—what has it done elsewhere? Long after the Mohammedan wave of conquest swept through Sind to the Punjab in the eighth century A.D. we know that a Buddhist province of Sind (called Bodh) still retained its infidel proclivities, and the capital of it (Gandhar or Kandhar) is not far from the Gandāva of to-day. Buddhist priests had ruled at Las Bela, where Buddhist caves are to be found near by. Was this the last stand made by Buddhism on the Indian side of the mountains west of the Indus?

There is a passage in the book which might be misunderstood. It is said of the fifteenth of the sixteen "Great countries"—or Powers—that

"Gandhāra, modern Kandahar, was the district of eastern Afghanistan, and it probably included the north-west of the Punjab. Its capital was Taxila."

Gandhāra *was* the north-west of the Punjab (as rightly shown in the little sketch map at the end of the book), but it had nothing to do with "modern Kandahar," or even with that other ancient Kandahar (or Kandhar) of which we have just spoken. It was the almost universal goal of the pilgrims from China who flocked in large numbers through the then open routes of Takla Makan in Chinese Turkesan, across

the Hindu Kush, and through the terrible passes and defiles of Darél to the lower Swat Valley and to the monasteries and monuments of the Punjab.

It would have been interesting, too, if something of the northern art of Buddhist India had been illustrated, as well as the sculptures of Sanchi. It is in the north that the Greek influence is so marked in sculptural art as to render it quite distinct in character from the rude and riotous productions of the indigenous artist of the south, probably educated in Hindu schools.

But it is impossible within the limits of a popular historiette to compass more than a cursory account of so astonishing a moral phenomenon in the world's history as the rise of Buddhism and its marvellous outspread; or to present a view of Indian existence other than that which marked certain phases of its career. Prof. Rhys-Davids has done invaluable service in illustrating the earliest phase of Buddhist inception, and in giving to the world a far more lucid idea of the character of the three great Buddhist kings and heroes —Chandragupta, Asoka, and Kanishka—than is to be found elsewhere in the popular literature of the day. For it is only a great scholar who could have done this so well.

The work is scholarly throughout, as well as popular, and fully maintains the high standard of the fascinating series of "stories" of which it forms a noteworthy unit.

ACETYLENE.

Acetylene: its Generation and Use. By F. H. Leeds and W. J. A. Butterfield. Pp. x+276. (London: C. Griffin and Co., Ltd., 1903.) Price 5*s.* net.

THE steady advance made during the past few years by this beautiful illuminant fully justifies the production of the practical handbook which Messrs. Leeds and Butterfield have now placed before the public.

In this work they have described and explained the physical and chemical phenomena attending the generation and combustion of the gas, and also its employment in the various directions in which it has of late been used.

The subject is thoroughly dealt with, and the book contains an enormous amount of information and common-sense advice, the only general criticism that can be urged against it being, perhaps, that of the occasional repetitions which are inseparable from dual authorship.

In the introductory chapter, whilst considering the advantages of acetylene as an illuminant, the authors deal with a point which, up to the present, has been too much overlooked with regard to illumination by flames, and that is the importance of the action that these have in burning up and destroying considerable quantities of the organic impurities present in the air of an inhabited room, a function which is of the utmost importance, and the absence of which is a considerable factor in the unpleasant nature of the atmosphere often found in rooms lighted by incandescent electric lamps.

An interesting feature is also to be found in the authors' attempt to compare the relative merits and cost of lighting by various illuminants on the basis of illuminating effect rather than illuminating power. That this difference does exist as a most important factor in illumination has long been recognised, and a moment's consideration will convince anyone that although a particular burner may yield a light of 25 candles, it will not be in any way equivalent in its power of effectively lighting a room to 25 candles distributed over the area of the room. If a satisfactory unit of comparison and an accurate method of determining the results could be obtained, this method of comparison would offer enormous advantages over the ordinary photometric method.

In compiling the table the authors have taken as the standard of a well-lighted room the being able to read with ease ordinary print in every part of it, but it is clear that so much depends upon the personal factor that whilst one observer may look up a train in Bradshaw with ease and comfort, another might find a difficulty in dealing with fair-sized print, and on such a basis it is hard to found a satisfactory unit of comparison.

In dealing with the physics and chemistry of the actions taking place between carbide and water in the generation of acetylene, the whole question is very carefully and thoroughly treated, but in referring to the power of water in dissipating the heat generated during the action, a little too much stress is laid on the power of water in keeping down the temperature. The statement that

"if an excess of water is employed in an acetylene generator the temperature inside can never, except quite locally, exceed 100° C. however fast the carbide be decomposed"

is although perfectly correct, a little misleading. The importance of reducing the temperature in an acetylene generator to the lowest possible point is to prevent the formation of certain compounds which afterwards give rise to trouble in the consumption of the gas, and with a large generator of the type in which carbide is fed into water, although the water may be in very large excess, it is by no means unusual to find in the centre of the decomposing mass on the bottom of the apparatus a temperature capable of melting lead, this being due to the fact that when the carbide is fed in in large quantities, a crust of lime forms on the outside of the mass which becomes toughened by tarry products formed by the heat on the acetylene generated in the interior of the mass, and this partly by acting as a non-conductor and partly by keeping the carbide away from the large excess of water, allows an undue rise of temperature, and the acetylene generated is found as a result to contain considerable amounts of products of polymerisation.

In referring to the combustion of acetylene and its illuminating power, the authors conclude that it would be clearer to state the illuminating power of acetylene as 48 candles per cubic foot, rather than by accepting the arbitrary nomenclature of gas photometry to speak of it as 240 candles, inasmuch as in determining the illuminating power, the gas has to be burnt at the rate best suited for developing its light-giving properties, and the results so obtained calculated to a consumption of 5 cubic feet.

It is not clear, however, that the statement of 48 candles per cubic foot would not be equally misleading, as the light emitted from good acetylene burners varies enormously with the rate at which the gas is consumed, so that with small burners the illuminating value of the gas is rarely more than 20 candles a foot, whilst with 1-foot burners it is a remarkably good burner that gives 42 candles per cubic foot of gas consumed.

In referring to the formation of carbonaceous growths at the burner tips, the authors point out that although this has been put down to the action of heat on polymerisation products in the acetylene, yet that if this were the case the trouble should disappear entirely if the gas were washed with heavy oil before entering the burners, this procedure, however, not giving entire freedom from the trouble. In this criticism, however, they evidently overlook the fact that not only does polymerisation of the acetylene take place where there has been undue heating in the generator, but that no matter how thoroughly the gas may be purified before reaching the burner, a further, though small, polymerisation will take place in its flow through the heated steatite tips at which it is burning, and that the trace of benzene so formed is quite capable of giving the trouble.

The practical details given as to size of pipes and other points upon which little or no knowledge exists amongst generator makers are of the greatest value, and the book may be most heartily recommended to all interested in the production and use of acetylene.

THE TSETSE FLIES.

A Monograph of the Tsetse Flies (Genus Glossina, Westwood). Based on the Collection in the British Museum. By E. E. Austen, with a Chapter on Mouth-Parts by H. J. Hansen, Phil. Doc. Pp. ix+319. (London: Printed by Order of the Trustees, 1903.) Price 15*s*.

SOME fifty years ago J. O. Westwood gave a description of a "destructive species of dipterous insect known under the name of Tsetse," and referred it to the genus Glossina, first established twenty years previously by Wiedemann. From that time onwards references to the tsetse fly and its association with a mysterious disease fatal to horses, cattle, and other animals become very numerous in the writings of travellers and naturalists, and various were the theories propounded to explain the relation of the fly to the disease. Drysdale, in 1879, seems to have been the first to suggest that the tsetse fly disease might be of an infective nature, the infecting agent being conveyed by the bite of the fly. In 1895 and 1897 the well-known reports of Lieut.-Colonel Bruce appeared. He described the tsetse fly disease or nagana met with in Zululand, and established the fact that it is due to a protozoan blood parasite, the *Trypanosoma Brucei*, which is conveyed by the bites of the tsetse fly from affected to healthy animals. As horses and cattle are unable to exist in the districts inhabited by the fly, the problem of transport in these "fly belts" is a serious one, and the tsetse fly and its distribution have assumed great economic importance. In India and Burma there is a similar, if not identical, disease known as surra, which is also conveyed by a biting fly, perhaps a species of Stomoxys.

Within the last few months evidence has been accumulating, through the work of Castellani, Bruce and others, that sleeping sickness, the ravages of which have assumed alarming proportions, may be caused by a trypanosome (*T. Castellanii*) attacking the central nervous system (see NATURE, vol. lxviii. p. 116).

From analogy with nagana and other facts (see NATURE, vol. lxix. p. 34) it would seem probable that a tsetse fly conveys the infection in this disease, and therefore that measures of prevention and extermination directed against the fly might stamp out sleeping sickness. Other diseases also, *e.g.* trypanosoma fever, are caused by species of trypanosomes, and these, too, may very likely be conveyed by tsetse flies.[1]

In view, therefore, of the practical importance of an accurate knowledge of the genus Glossina, the Trustees of the British Museum have been well advised to publish this monograph upon the tsetse flies, the preparation of which has been entrusted to Mr. Austen. We may say at once that Mr. Austen has produced a work which must for some time remain the standard one upon the subject. He gives both a popular and a scientific description of the flies, a full bibliography with copious abstracts, the whole being illustrated with many figures in the text, with a map showing the geographical distribution, with beautiful coloured plates of the seven known species from drawings by Signor Terzi, and with two plates of the mouth-parts of Glossina and Stomoxys. The latter, together with a description, are by Dr. Hansen, and will enhance the value of the volume to the dipterologist.

In the first place it is to be noted that, although the term "the tsetse *fly*" is usually employed, there are at least seven species, so that "tsetse" becomes a *generic* rather than a specific name. By some the original *Glossina morsitans* has been called the "true tsetse." The name "tsetse" is of obscure origin, but is certainly onomatopoetic, derived from the peculiar buzzing sound made by the fly on the wing. The tsetses are confined to Africa, are always met with in the neighbourhood of water, and are often restricted to peculiarly well-defined tracts of country. Mr. Austen's description of them may be reproduced here, since NATURE may reach many who may not have access to this monograph:—

"The tsetses are ordinary-looking sombre brownish or greyish-brown flies varying in length (excluding the proboscis) from $3\frac{1}{2}$ to $4\frac{2}{3}$ lines ($7\frac{1}{2}$–10 mm.) in the case of *Glossina morsitans* to about $5\frac{1}{2}$ lines ($11\frac{1}{2}$ mm.) in the case of *Gl. fusca* or *longipennis*, with a prominent proboscis in all species. The hinder half of the body, or abdomen, in the best known species, though not in all, is of a paler colour and marked with sharply defined dark brown bands, which are interrupted on the middle line; the abdomen, however, is invisible when the insect is at rest, as it is then concealed by

[1] Since the above was written, a further report on sleeping sickness by Col. Bruce has been issued. In this much additional evidence is given of the correctness of these views of the nature of sleeping sickness and of its transference by a tsetse. Trypanosoma fever may be the early stage of sleeping sickness.

the wings. . . . In *the resting position* their identification is easy. In this attitude they can be distinguished from all other blood-sucking Diptera . . . by the fact that the brownish *wings lie closed flat over one another down the back*, like the blades of a pair of scissors, while *the proboscis projects horizontally in front of the head*" (p. 3)

There is one peculiarity of *Gl. morsitans* that may be noted, viz. it does not lay eggs as do the majority of the Diptera, but extrudes a yellow-coloured larva nearly as large as the abdomen of the mother. Whether this process is the same in all species has yet to be determined. Of the seven species of tsetse described, one (*Gl. pallidipes*) is new, and appears to be the East African representative of *Gl. longipalpis*. The work concludes with some valuable appendices of information from travellers, Government reports, the reports of Colonel Bruce and others.

When the transmission of malaria by the mosquito was proved, the authorities of the British Museum rose to the occasion and published the magnificent monograph upon the Culicidæ by Mr. Theobald; again they have not disappointed us. In conclusion we would direct attention to the series of models in the entrance hall of the Natural History Museum of the trypanosome and tsetse fly, and of the malaria parasite and mosquito; they should be studied by all who may have the opportunity of increasing our knowledge of these and other tropical diseases.

R. T. H.

METALLURGY OF STEEL.

Hardening, Tempering, Annealing, and Forging of Steel. By Joseph V. Woodworth. Pp. 288. (Westminster: Constable and Co., Ltd.) Price 10*s*. net.

TO students who have ploughed through the weary sands of recent steel literature, Mr. Woodworth's book will appear somewhat in the nature of an oasis in the desert. The author does not appear to be versed in the "ites" of metallography, or fully to have grasped the allotropic theory of hardening, but, nevertheless, he does thoroughly understand tool-steel. Authors of papers on the restoration by heat treatment of faulty steel will hardly be prepared to acquiesce in a statement made by Mr. Woodworth on p. 18 of his book, namely,

"Heating for forging is, in its way, quite as important as heating for hardening; care and uniformity in the application of heat in the first instance is very essential. Should the steel be over-heated in this process, no amount of care afterwards will restore the steel to its former state or remedy the evil."

With the words above quoted everyone who has had an extensive practical experience of steel metallurgy will be more than inclined to agree.

On p. 24 attention is directed to the fact that steel as delivered from the manufacturer is always more or less decarbonised on the surface.

"For this reason, do not select a piece of steel which will just 'skin' up, but take a piece large enough to require taking a good-sized cut before reaching the finished surface."

This is good advice, not only to mechanics, but also to scientific men making researches on the magnetic properties of steel. Mr. Woodworth, in concise and lucid terms, deals at considerable length with the machining, hardening, and tempering of nearly every class of steel tools, and the value of his letter-press is enhanced by a series of admirable illustrations (chiefly in perspective) of turning tools, taps, reamers, and an excellent set of milling cutters.

A brief illustrated article on muffle furnaces (pp. 92–94) is well worth the attention of British artisans, as showing American practice, which is, on an average, undoubtedly superior to that obtaining in this country.

That portion of Mr. Woodworth's book dealing with the manufacture of dies and of drop forgings must necessarily be interesting to British manufacturers and workmen, because America was the birthplace of drop forgings, which were first manufactured by Colonel Colt, of revolver fame, in 1853.

Another feature of the work now under review is the fairly complete and beautifully illustrated chapter on the emery-grinding of steel tools. Mr. Woodworth advocates as the highest type of forgings material which has been quenched in oil and subsequently tempered to remove contraction stresses. The views he expresses have already found favour with many experienced British steel metallurgists.

On p. 162 Mr. Woodworth leaves, for the time being, a branch of steel metallurgy in which he is evidently a past master, and becomes controversial on the well-worn argument of steel *v.* wrought iron forgings. In deciding upon the superiority of steel, the author perhaps a little overdoes it, and his quotation from the report of the American Government tests on alternating stresses will hardly convince steel metallurgists who have closely studied this matter.

The tests he quotes show that wrought iron is capable of enduring only 50,000 alternations. Steel, with 0·25 per cent. of carbon, endures, before fracture, 229,000 alternations, whilst steel with 0·45 per cent. of carbon sustains almost a million alternations. The author considers that these figures

"have given engineers an idea of the comparative endurance of wrought iron and steel in such service as that to which crank-pins, shafting, &c., are subject."

Had Mr. Woodworth seen a verbatim report of the trial to decide the cause of the disaster on H.M.S. *Bullfinch*, which occupied several days at the King's Bench in the summer of 1902, he would probably have expressed a much modified opinion on the question at issue. Broadly speaking, the connecting rods of the *Bullfinch* were of the higher carbon limit just quoted; the rods of H.M.S. *Snapper* contained about the lower limit mentioned, namely, 0·25 per cent. of carbon. The rods of the *Bullfinch* snapped on her trial trip, causing lamentable loss of life. Those of the *Snapper* were taken out intact after the destroyer had run her trial trips and been four years in commission.

An interesting portion of this book is the description of the Taylor-White process, which was the pioneer of those steels known as "speedy-cut," but quite naturally Mr. Woodworth does not specially direct

attention to the fact that since the inauguration of this process its product has been distinctly eclipsed by steels manufactured in several famous Sheffield works.

Mr. Woodworth's book has been written by an able man, thoroughly interested in his craft, and it is to be hoped that it will find its way into the hands of a large number of British artisans.

J. O. ARNOLD.

OUR BOOK SHELF.

Macedonian Folklore. By G. F. Abbott, M.A. Pp. xii+372. (Cambridge: University Press, 1903.)

THIS somewhat dainty little volume on Macedonian folklore, with its blue and white binding, will be welcomed by many readers, first, because the print and paper are good, and next, because the work is pleasantly written, and every paragraph is of interest. The results collected in the work before us by Mr. G F. Abbott, of Emmanuel College, Cambridge, are the fruits of a series of researches into the folklore of the Greek-speaking parts of Macedonia, carried on by the author under the auspices of the electors to the Prendergast studentship of the governing body of Emmanuel College, Cambridge, and there can be no doubt that the materials here gathered together amply justify the selection of Mr. Abbott for his mission by the powers that be.

The reader or student who is familiar with the sound and solid work of Prof. E. B. Tylor, and the wonderful volumes of his friendly rival, Mr. J. G. Frazer, will not expect to find in this monograph the vast knowledge and mature thought which are so characteristic of the works of these eminent scholars, but it is pleasant to see that the influence of both of them is visible in Mr. Abbott's treatise, and we therefore look forward to other works from his pen with confidence. "Macedonian Folklore" contains nineteen chapters, six appendices, and an index; the last-named section is very short, and we think it should have been made fuller. After a short description of the sources of the facts which he prints, and a narrative of some amusing personal experiences, Mr. Abbott proceeds to deal with the folklore of the Macedonian year, which he treats in four chapters. Many of the saws are familiar enough to us in other forms, but there are several auguries and prophecies about the weather which are worthy of note for comparative purposes.

The section on divination is of considerable interest, and it seems that the Macedonians divine by means of coffee, instead of by tea as Europeans in the west do. The expert will have no difficulty in tracing a connection between some of the divination practices here described with those of many nations, but there are many which have no parallels among other peoples, so far as we know, and these, of course, form one of the most valuable parts of Mr. Abbott's book.

The chapters on birth, marriage, and funeral rites are lengthy, but very interesting, and the numerous extracts which we have from the songs of the people enable us to judge of the accuracy of the deductions set forth in them. The original Greek is given, in all cases, with an English translation, and this plan is a handy one and one to be commended. We cannot refer to details, for want of space forbids, and we therefore pass on to mention the chapters on Alexander the Great and Philip in folk-tradition, to the series of pretty bird-legends which are printed on pp. 291–294, to notes on the game of morra, fire-ordeal, the perils of portraiture, &c., and to the collections of riddles, mystic poems, love-couplets, &c., which bring the book to an end. Mr. Abbott's contribution to the science of Macedonian folklore is opportune, and the modesty of the work and the care with which it has been performed merit praise.

Practical Physics for Schools. I. Mensuration, Mechanics, and Hydrostatics. Pp. 72. II. Light and Heat. Pp. 79. By C. J. L. Wagstaff, M.A., and G. C. Bloomer, B.A. (Cambridge: W. Heffer and Sons, 1903.) Price 1s. 6d. each.

THE authors say in their preface that these notes have been used for the teaching of practical physics at the Bradford Grammar School during the last three years, and the presumption is that experience has proved their usefulness and suitability. An examination of the volumes, however, suggests that the notes have in practice probably been supplemented by judicious additions by the teachers, or the results of the instruction would have been less satisfactory. The volumes contain no illustrations to show pictorially the arrangements of the apparatus described; one page only seems to be devoted to the plotting of curves, and on this page there is by no means enough explanation to explain to a young student the method and meaning of such graphic representation; and, more than this, under the section Boyle's law, the pupil is instructed to plot a curve connecting P and 1/V, and in another place to plot a curve connecting the square root of the length of a pendulum and the time of swing, though the only remarks on curve plotting, instead of preceding these instructions, follow in another experiment. In several places, too, the verbal instructions seem inadequate to the needs of beginners. In describing the screw gauge the authors content themselves by saying that the zero error must be ascertained carefully, and give no directions as to how this should be done. The account of the vernier is similarly too brief. To secure the best results in a physical laboratory the student should be in possession of directions explicit enough to avoid the waste of time caused by waiting for the master to arrive to clear up a difficulty, and these directions should be obtainable from the book or be given in a preliminary demonstration. Notwithstanding the remark of the authors that experimental work in sound is only suitable for a later stage, there are many experiments in this branch of physics that interest young people and are understood by them. On the whole, however, the course is comprehensive and generally in accordance with the experience of good laboratory practice.

Flora of the Upper Gangetic Plain and of Adjacent Siwalik and Subhimalayan Tracts. Vol. i., part i. By J. F. Duthie, B.A., F.L.S. Pp. xvii + 403. (Calcutta: Office of the Department of Government Printing, 1903.) Price 15s.

IT is only by a very liberal interpretation of the term that this book can be referred to as a *local* flora, seeing that it deals with an area of 196,000 square miles, which includes not only the North-West Provinces up to the Subhimalayan slopes, but extends southwards to the Vindhaya Mountains, and thus takes in portions of some dependent States. But as a comparative term, when contrasted with Sir J. Hooker's "Flora of British India," the expression has been applied both to this flora and also to Dr. T. Cooke's "Flora of the Bombay Presidency." A very satisfactory feature of the book is the facility which is offered for obtaining information quickly and easily. A synopsis of the natural orders is given, arranged on principles similar to those which are so well known from Hooker's "Student's Flora," arrangement being based primarily on the characters of the ovary. For each order and genus full descriptions and determining keys are provided, and for the species references, synonyms, locality

and distribution are added. These, in conjunction with a glossary of terms, render the book available to everyone possessed of an elementary knowledge of botany. In addition to the descriptive text, Mr. Duthie has collected into the notes appended to the species a vast amount of information dealing with the identification and economic uses of the plants, both indigenous and cultivated. A perusal of the book not only serves to indicate how large a proportion of the Indian plants possess valuable properties, but also cannot fail to impress one with the comprehensive knowledge which has been acquired by the assiduous work of the author and other botanists in India who have occupied similar responsible positions. This part includes the orders Ranunculaceæ to Cornaceæ; the first volume will extend to the Campanulaceæ, and two volumes will complete the work.

A Laboratory Guide to Qualitative Analysis with the Blowpipe. By F. W. Martin, Ph.D. Pp. iv+47. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1903.) Price 2*s.* 10*d.*

THE author regards the restricted employment of the blowpipe in analysis as due to the lack of a convenient manual or work of reference, which this modest little volume of fifty pages is now intended to supply.

It may be questioned whether, in a well-equipped laboratory, the use of the blowpipe as a delicate instrument for qualitative analysis will supersede other methods. For the mineralogist, and especially for the mining prospector, the classic of Plattner-Richter, which has been translated into English by Cornwall, will always hold its place.

There is nothing in the present volume to call for special notice. The matter is very condensed, occasionally at the risk of becoming confused. This is a description of a coal gas flame:—"Its luminosity is due to superheated, separated carbon set free from acetylene, an easily decomposed gas, which is formed from other hydrocarbons composing the gas used as fuel by the heat of combustion in the outer envelope." One is accustomed to the American spelling of "luster," "vapor," &c., but the omission of the final e in "oxid," "sulfid," "chlorid," &c., if intentional (*oxide* also occurs), is un-English.

J. B. C.

Elementary Experimental Science. Physics. By W. T. Clough. *Chemistry.* By A. E. Dunstan, B.Sc. Pp. vi+239. (London: Methuen and Co., 1904.) Price 2*s.* 6*d.*

THE course of work provided in this little book is intended for young beginners who propose to present themselves for examinations of the standard of the University Junior Locals. The book aims at supplying the necessary general information, and also sufficiently explicit instructions for laboratory work. In the physics section 157 experiments are provided, and in chemistry there are 110, but a number of them are more suitable for lecture demonstrations than for laboratory exercises. A pupil who works through the book, performing the more important of the experiments given, cannot fail to obtain a fair knowledge of the fundamental principles of physical and chemical science.

Notes from a Lincolnshire Garden. By A. L. H. A. Pp. 93. (London: Elkin Mathews, 1903.) Price 2*s.* 6*d.* net.

THESE notes are chatty, interesting, and intelligent. The writer loves the garden and everything that happens in or near it. The book is an instance of the humanising effect of nature-study undertaken for the love of the subject. The little book may be recommended to all lovers of country gardens.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Heating Effect of the Radium Emanation.

IN a letter to NATURE of November 5, Prof. Schuster has made some remarks on a letter published by us the week previously, containing a brief account of some experiments to show that the heating effect of radium is temporarily reduced by the removal of the emanation, and that the tube containing the emanation separated from the radium shows a considerable heating effect.

The difficulty felt by Prof. Schuster apparently arose from the fact that we included in the heating effect of the emanation not only that due to the emanation itself, but also that due to the secondary products to which the emanation gives rise. It was an oversight on our part to have omitted in the sentence "more than two-thirds of the heating effect is not due to the radium at all, but to the radio-active emanation which it produces from itself," the words "together with the secondary products to which the emanation gives rise." We were fully aware that the heating effect was in part due to the "excited activity" produced by the emanation. We specially mentioned the gradual decay of the heating effect of radium to a minimum in the course of a few hours, and the increase of the heating effect of the emanation tube during the same period. These effects are connected with the gradual decay and rise, respectively, of the excited activity produced by the radium emanation. The results would have little meaning if we believed the heating effect was due to the emanation alone, for, as Prof. Schuster quite correctly points out, the heating effect in such a case should at once drop to a minimum after removal of the emanation, and the heating effect of the tube containing the emanation should not at first increase.

On account of the rapid rise of the excited activity in a tube containing the radium emanation, the separation of the heating effect of the emanation from the complicated secondary changes which result from it is a difficult experimental problem.

Our letter was merely a preliminary announcement of the results of our experiments. It is not possible to discuss the consequences to be deduced from the experiments without entering into a detailed description of the measurements. We hope to publish shortly a full account of our work on the various heating effects.

McGill University, November 20.

E. RUTHERFORD.
H. T. BARNES.

The Pearl-Oyster Parasite in Ceylon.

MR. JAMES HORNELL, who is still in Ceylon carrying on the investigation of the pearl-oyster fisheries which I started in 1902, tells me in a letter just received that he has now succeeded in finding the final stage of the cestode larva which we found to be the nucleus of the best Ceylon pearls. We found this larva (a Tetrarhynchus), in the spring of 1902, in the pearl-oyster, and, later on, what we took to be its later stages in the file-fishes (Balistes) which feed upon the pearl-oysters, and we felt pretty certain (as I stated in the first part of my report, now published) that the adult would be found in Trygon or some other large Elasmobranch. Mr. Hornell writes from Trincomalie, November 16, as follows:—"Just a line to tell you that I have found the final host of *Tetrarhynchus unionifactor*.[1]

"It occurs, as surmised, in one of the large rays—a Trygon, I believe, but I have no work on fishes, and cannot identify at present.

"There is, I believe, practically no doubt as to species, in the stomach of the ray being two Balistes entire, and apparently just devoured, and plenty of bones. In the folds

[1] The name we gave to this Tetrarhynchus larva in our notes and letters until it was ascertained whether the species was known or new.—W. A. H.

of the spiral valve various Tetrarhynchids, *mature*, of two sizes—I fancy of [two] species—which bears out Shipley's belief of 2 species being in Balistes. In the stomach a larval Tetrarhynchid just where a larva should be—the adults being further along the canal."

The rest of the letter, hurriedly written to catch the mail, refers to other matters.

Mr. Arthur Shipley, who is writing a joint paper with Mr. Hornell on the parasites of the pearl-oyster for my report, will no doubt discuss the matter fully later on, when he has examined the specimens, but it is, I think, only due to Mr. Hornell, who is working most energetically in the wilds far from books of reference or any other scientific help, that his interesting announcement should be made public as soon as possible. W. A. HERDMAN.

University, Liverpool, December 9.

The Late Leonid Meteor Shower.

SUSPECTING that the tail or following segment of this swarm, owing to its enormous length, might be outside the sphere of influence of Saturn in 1870, and Jupiter in 1898, the writer kept watch as follows to see how far this suspicion might prove to be correct :—

Friday morning,	November	13,	... ...	Overcast
Saturday ,,	,,	14,	3 to 4	No Leonids
Sunday ,,	,,	15,	12 to 2.30 ...	2 Leonids
			5 to 5.30 ...	No Leonids
Monday ,,	,,	16,	12 to 4.15 ...	Intense shower
Tuesday ,,	,,	17,	... .	Overcast
Wednesday ,,	,,	18,	5 to 5.30 ...	3 Leonids

One of the two Leonids observed at about 12.30 on November 15 diverged with a long, slow motion from Zeta Leonis to below the stars Nu and Zeta, Ursa, giving one the impression of its being an almost "end on" one from near the radiant, while the other, at about 2 a.m., passed high up on the right with a bright flash or streak. A further short watch was kept from 5 to 5.30 with no results; hence the conclusion that the shower would be of no very imposing character. This, however, proved to be incorrect, as on the following morning, November 16, at 12.30, a bright flash overhead, and shortly afterwards two fine meteors diverging right and left from a point near Zeta inside the Sickle, indicated increased activity.

The display rapidly increased, the meteors coming apparently in little flocks or shoals, the majority from an area of, say, 6 degrees by 3 degrees along Leo, with an hourly rate which he estimated as high as from 80 to 100, but this would seem to be below the mark. Between 3 and 4 a.m. several bright meteors diverged upwards and downwards from the Sickle, thus enabling him to fix the radiant as close by its old position at $149° + 22°$. The following morning, November 17, was overcast, but the radiant was still active on November 18, one of the three Leonids observed radiating upwards over Eta from within the Sickle as usual. A remarkable feature was that many of the meteors diverged upwards towards the S.W., whilst others diverged downwards N.E., as if conforming to the ecliptic, an appearance which may have been due to the rotation of the earth, and had been noticed before in connection with other well-known showers. Many of the larger meteors lit up the atmosphere with fine, bright, steel-like flashes.

At 4.15 the sky became overcast, but as he turned in he could still see meteors falling in the west and north-west, and it would appear, from observations made elsewhere, that the maximum occurred during the next two hours, *i.e.* from 4 to 6. It may here be remarked that this shower seemed in previous years to be at its best about an hour or so before daylight, owing, no doubt, to its then high altitude.

Altogether, the display was much above the average, and would appear to have justified the anticipation that the tail end held on its course. At any rate, we get another glimpse into the mechanics of a meteor stream, and more particularly into that of the Leonid, and the distribution around the orbit of the latter, should it still intersect the path of the earth, is a question for the future.

W. H. MILLIGAN.

2 Barronville, Holywood, Co. Down, November 30.

MR. HENRY's letter in your issue of November 26 contains several notable points which confirm my own observations. Being engaged on other work (which entailed long spells within the observatory and the dark room) throughout the night of November 14 and early morning of November 15, I noticed only a few meteors, and, as the sky became overcast here at 4.45 a.m., it is evident that, according to Mr. Denning's account, observations of the maximum display were impossible at South Kensington.

However, on the early morning of November 16, 2.15–3.50 a.m., my watch was rewarded by the appearance of more than fifty Leonids, some of which were exceedingly bright and lasting. Facing the south-east, I had familiar constellations (Orion, &c.) in the field of view, and was consequently able to record the trails among the stars with a fair amount of certainty.

The most striking point on which Mr. Henry's observations are confirmed by mine is that there were decidedly *two* apparent separate radiants, the one very near to, or coincident with, that given by Mr. Denning in NATURE for November 12, and another, from which quite half of the observed meteors seemed to emanate, at about R.A. $= 145°$, Dec. $= +17°$. Several Leonids with short trails were seen quite near to "the Sickle," and indicated by their direction the existence of this second radiant point. One long-trail Leonid occulted ξ Geminorum, and if the trail had been prolonged (it stopped short about two or three degrees from Betelgeuse) it would have passed between α, γ, and $\lambda\phi$ Orionis. The majority of the meteors observed by me passed from the direction of Leo towards Gemini, Orion, or Canis Minor. WILLIAM E. ROLSTON.

Solar Physics Observatory, South Kensington, S.W., December 5.

Weather Changes and the Appearance of Scum on Ponds.

SOME years ago I also observed the phenomenon of a sudden appearance of scum on the surface of a pond similar to that mentioned by "Platanus orientalis" in NATURE, November 5.

The explanation, however, given by Dr. Mill in the same number of NATURE, namely, that the appearance of scum is occasioned by an accelerated flow of springs rising through the chalk of the floor of the pond, does not apply to the case which I have observed. That pond had no springs of the kind, but was fed by a very small and slow creek emptying into the pond at its upper extremity. Although the pond was pretty large, the scum did not appear near the inlet only, but all over the pond at the same time.

I wish to offer the following explanation of the phenomenon so far as it came under my observation, and I am inclined to believe that it applies to the case of "Platanus" just as well.

Our pond was very rich in marsh gas, a fact which could be easily ascertained by thrusting an oar into the soft bottom, when large bubbles of this gas would come to the surface. Now it is quite natural that this gas, slowly generated as it is, within the layer of decaying vegetable matter at the bottom of the pond, will gather in little bubbles, and these in turn will rise, provided they have acquired a sufficient buoyancy to break through their mouldy matrix, tearing off and carrying some of the solid matter up to the surface.

Ordinarily, this will take place all the time at regular intervals, but at a very slow rate, and would, therefore, escape observation. In time of a sudden fall of atmospheric pressure, however, the case is different. Then all the gas bubbles which are more or less ready to rise under normal conditions will suddenly expand and rise simultaneously, carrying upward not only a few isolated particles, but entire layers of soft material. I have often observed this very phenomenon, although I failed to notice the atmospheric condition at the time.

The material itself which was thus thrown to the surface consisted, so far as I can recollect, of black-brown vegetable matter, derived chiefly from leaves that had fallen into the pond, and of a green slime, consisting of numerous algæ.

FRED. J. HILLIG.

St. John's College, Toledo, Ohio, U.S.A.

SOME SCIENTIFIC CENTRES.

VI.—THE CAVENDISH LABORATORY.

SINCE its foundation, the Cavendish Laboratory of Cambridge has held a very prominent position, not only as the home of the teaching of physical science in one of our great universities, but also as the centre of a vigorous and prolific school of scientific research. The history of the laboratory must always be intimately associated with the scientific labours of the three distinguished holders of the chair of experimental phyics in the University of Cambridge, J. Clerk Maxwell, Lord Rayleigh, and J. J. Thomson, each of whom, in his own direction, has exerted an unusually marked influence in the advance of physical science.

The laboratory is of relatively recent foundation in comparison with some of our older scientific centres like the Royal Institution, but yet it may claim to be one of the first of those modern laboratories which have now sprung up in almost all the larger universities where adequate provision is made for the advancement of scientific research as well as for the teaching of science. In 1870 the Duke of Devonshire, who was then chancellor of the university, signified his desire to build and equip a physical laboratory for Cambridge. In his capacity as member of the Royal Commission of Education, he had recognised the value of such an institution. The chair of experimental physics was founded as a result of this offer in 1871, and in the same year James Clerk Maxwell was appointed to the position. It was enacted that it should be "the principal duty of the professor to teach and illustrate the laws of Heat, Electricity, and Magnetism; to apply himself to the advancement of the knowledge of such subjects; and to promote their study in the University."

For several years after his appointment Maxwell was occupied in designing and attending to the construction of the laboratory, and equipping it with suitable apparatus. The building was not ready for work until 1874, when the chancellor of the university formally presented his gift to the university.

The laboratory is an unpretentious solid three story building of stone. At the present time the ground floor is taken up partly by a series of rooms devoted to research and by a large and admirably equipped workshop and a small battery room. One of these rooms was for many years used by Dr. Glazebrook, secretary of the British Association Committee of Electrical Standards, as a standardising laboratory, and here were kept the electrical standards of the Association. On the walls, as one ascends the stone stairway, hang a painting of the founder, a picturesque print of Cavendish, that eccentric man of science who did such admirable electrical work more than a century ago, a small painting of Maxwell, and fine enlarged photographs of Lord Rayleigh, Sir George Stokes, and Lord Kelvin. The first floor is occupied by a large laboratory for practical work, a lecture and preparation room, and a neatly arranged apparatus room. Here are kept some scientific apparatus of unusual historic interest, including the original British Association revolving coil, with which the first determination of the value of the ohm was made, the revolving coil used by Lord Rayleigh for the same purpose, and the oscillation apparatus used by Maxwell in his determination of the viscosity of gases. Among many other pieces of apparatus devised by Maxwell may be mentioned his model for illustrating the induction of electric currents, and spinning tops and plaster casts made by his own hands to illustrate Willard Gibbs's heat surfaces. The second floor consists of a laboratory devoted to advanced practical work and four research rooms. In 1896, on account of lack of accommodation, another wing was built to the laboratory. This includes a large well-lighted laboratory devoted to the practical work in physics of the medical students, a small lecture room, several smaller research rooms, and a basement which can be used as a constant temperature room.

The laboratory, at the time of its foundation, was one of the largest and best equipped then in existence. The fame of Maxwell immediately attracted round him men eager to undertake research under his guidance. Among others, it is interesting to recall the well-known names of Chrystal, Garnett, W. D. Niven, Schuster, and Gordon. One of the first pieces of important research undertaken in the laboratory was a verification of Ohm's law by Chrystal. The experiments of previous observers and Weber's theories had thrown doubt on its validity, but Chrystal showed that the law held with great accuracy over a wide range, and he was able also to explain the apparent discrepancies observed by others. Maxwell himself during his tenure of the professorship was mainly occupied in superintending the work of others, in preparing for the press his celebrated treatise on electricity and magnetism, his treatise on heat, and in the editing of the Cavendish papers. The "small book on a great subject" entitled "Matter and Motion" was also published during the same period. The greater portion of his energies during the closing years of his life was devoted to the editing of the electrical researches of the Hon. Henry Cavendish, F.R.S., great uncle of the Duke of Devonshire, the founder of the laboratory. Cavendish, at his death, had left behind a mass of unpublished manuscript containing an account of his electrical researches. An examination of these papers showed that Cavendish was far in advance of his time in knowledge of electricity, and had made many important discoveries.

Although Maxwell did not find time to do very much experimental research in the Cavendish, his influence in directing the work of others and in infusing fresh life into the mathematical studies at Cambridge cannot be overestimated. In the "Life of Maxwell," Lord Kelvin, writing in 1882, gives the following important testimony:—"The influences of Maxwell at Cambridge had undoubtedly a great effect in directing mathematical studies into more fruitful channels than those in which they had been running for many years. His published scientific papers and books, his action as examiner at Cambridge, and his professorial lectures, all contributed to this effect; but, above all, his work in planning and carrying out the arrangements of the Cavendish Laboratory. There is, indeed, nothing short of a revival of physical science at Cambridge within the last fifteen years, and this is largely due to Maxwell's influence."

Maxwell's reputation, although great during his lifetime, has continued to grow steadily since his death. His work on the kinetic theory of gases, on dynamical subjects, and on the theory of colours was sufficient to place him in the very first rank of scientific investigators, but it is on his great work in electromagnetic theory that his fame will ultimately mainly rest. Maxwell's views of the electromagnetic field and his electromagnetic theory of light were generally accepted among English physicists, but on the Continent, where rival theories held the field, were practically unknown except to a few. The brilliant experiments of Hertz and others on the production and properties of electrical waves verified in a most conclusive manner Maxwell's theory that light was an electrical disturbance in the luminiferous ether. This gave a great impetus to the study of Maxwell's theory of the electromagnetic field, and it is safe to say that practically all the mathematical theory of the last

fifteen years on the subject has been based on Maxwell's fundamental equations, and is largely a result of his theoretical views.

On Maxwell's death (1879) Lord Rayleigh was appointed, and held the chair until 1884, when he resigned to take the place in the Royal Institution vacated by the retirement of Tyndall. His short tenure of the Cambridge chair was marked by a series of classical researches in the Cavendish Laboratory on the value of the electrical units. Lord Rayleigh undertook a determination of the three fundamental units, the ohm, the volt, and the ampere, and performed this work with an accuracy that has left little room for improvement. It is hardly necessary to speak here of his valuable work in this connection, which is so well known to every physicist, but it suffices to recall his experiments on the ohm with a modified form of the British Association revolving coil, his determination of the electrochemical equivalent of silver and the E.M.F. of the Clark cell by means of his current balance, and his determination with Mrs. Sidgwick of the specific resistance of mercury. At the same time he determined in absolute measure the rotation of the plane of polarised light of carbon bisulphide in a magnetic field. In addition to this electrical work, a number of optical papers of great value were written within this period. We have confined our attention to the work of Lord Rayleigh in the Cavendish Laboratory. To the great mass of valuable work produced before and after his stay in Cambridge (now collected and published in four large volumes) it is impossible even to refer in this short article.

On the resignation of Lord Rayleigh, J. J. Thomson was appointed, at the early age of twenty-six. Like his predecessors in the chair, Prof. Thomson is a product of the mathematical and physical school of Cambridge, first taking the mathematical tripos and then entering upon experimental work in the Cavendish Laboratory. His first piece of work, undertaken before his appointment, was a determination of "v"—that important ratio between the electromagnetic and electrostatic units to which so much attention was devoted before the verification of Maxwell's electromagnetic theory. This was followed by a notable piece of mathematical analysis dealing with the action of vortex rings on one another, which gained for him the Adams prize. In this paper he investigated with great mathematical power the stability of interlocked vortex rings, and showed that not more than seven could be linked together without breaking up into new arrangements—a result which probably indicates the reason why no element has a greater valency than seven. In this work we have the first evidence of the bent of J. J. Thomson's mind towards the study of the constitution of matter—a study to which he has devoted so much attention with such conspicuous success in recent years. Next followed the publication of a book on the application of dynamics to physics and chemistry—a notable work in which a general method of analysis, based on Lagrange's equations, was used to solve many recondite physical and chemical problems. Among these may be mentioned an investigation of the action of an electrified atom in causing the condensation of water vapour around it. This result has proved to be of great importance in connection with later work to be done in the laboratory.

The year 1887 saw the publication of a paper on the effect of a moving electrified sphere, not only remarkable for the direct results obtained, but for its indirect bearing on the question of the origin of mass. The results of a mathematical analysis showed that a moving charge of electricity possessed an apparent or electrical mass in virtue of its motion. This electrical mass was constant for slow speeds, but increased with great rapidity as the speed of light was approached until, at the velocity of light, it became infinite in value. The possibility that mass, which has been such a mystery to science, is due to electricity in motion has been recently brought much into evidence by the experiments of Kaufmann on the kathodic rays of radium. He has shown that the apparent mass of the particles constituting the kathode rays, spontaneously emitted by radium, increased with the speed in accordance with the theory first advanced by J. J. Thomson, and afterwards developed by Heaviside, Searle and Abraham. This result points to the possibility that the apparent mass of the kathodic ray particle may be accounted for by electricity in motion without the necessity of any material nucleus.

The following years were occupied partly with investigations on the electrodeless discharge, the electrification produced by falling drops of water and experiments on electrical oscillations, and also with the preparation for the press of a text-book on electricity and magnetism, and a splendid volume entitled "Recent Researches in Electricity and Magnetism." These two books are so well known to every physicist that no further mention is necessary here.

J. J. Thomson next definitely attacked the problem of the nature of the discharge of electricity through gases. A repetition of Perrot's experiments on the passage of electricity through steam and experiments in vacuum tubes led him to the view that, as in a solution, the passage of electricity through gases was accompanied by electrolysis. This theory has been modified with the growth of experimental knowledge to the view that the discharge in gases is due to the motion of charged carriers or ions. These ions are not necessarily identical with the corresponding ions in the electrolysis of solutions. There is no doubt that there is in many cases an actual electrolysis similar to solutions occurring in gases, but this seems to be the result of a secondary action.

A great impetus was given to the study of this subject by the discovery of Röntgen rays. These rays possess the power of making all gases temporary conductors of electricity. In a paper with Rutherford, J. J. Thomson advanced the view that the conductivity imparted to the gas by the rays was due to the production of positively and negatively charged ions in the gas. These ions travel in an electric field with a velocity proportional to the strength of the field. When no electric field is acting the ions gradually disappear by recombination amongst themselves. This theory was found to explain all the characteristic properties of the conducting gas. In the course of the next few years, as a result of the joint efforts of those engaged in research in the Cavendish Laboratory—among whom may be mentioned C. T. R. Wilson, Maclelland, Rutherford, Zeleny, Townsend, Langevin, H. A. Wilson, Maclennan and Strutt, and many more besides—the subject developed with great rapidity along two distinct lines. By purely electrical methods the ionisation theory of gases was shown to account for the conductivity of flames and vapours, the discharge due to ultra-violet light and to radio-active substances. At the same time the admirable experiments of C. T. R. Wilson on the detection of ions by means of their power of becoming centres for the condensation of water vapour upon them showed that charged ions actually did exist distributed throughout the gas, and were not a figment of the imagination.

During this time J. J. Thomson published a remarkable paper on the nature of the kathode rays. Since their discovery by Crookes, the nature of these rays had been the subject of what may almost be called an international controversy. The English school took the view that they consisted of a stream of matter projected with great velocity; the German school regarded them as a kind of wave motion in the ether.

The experiments of Crookes had shown they were deflected by a magnet, while Perrin much later showed that they carried with them a negative charge. If the rays consisted of negatively charged particles, they should be deviated by their passage through an electric field. Hertz had tried such an experiment, but with negative results. The remarkable experiments of Lenard and the connection in some way between Röntgen and kathode rays made the elucidation of the true nature of these rays a matter of the first importance. It was at this stage that J. J. Thomson attacked the problem. He showed that the rays were deviated by an electric field, and explained the cause of the failure of Hertz to detect the same. By two distinct methods he proved that the rays consisted of negatively charged particles projected with a velocity of about one-tenth the velocity of light. The value of the glowing carbon filament of an incandescent lamp, had the same value of e/m as the corpuscle in the vacuum tube. These results indicated that the corpuscle, or electron as it is sometimes called, was the protyle or fundamental unit of which matter is built up. He suggested that the atoms of matter were very complex systems, consisting of a great number of corpuscles and corresponding positively charged bodies. It is remarkable that corpuscles only carry with them a negative charge. The positive charge appears always to be associated with matter atomic in size.

This work was followed by a series of investigations in the laboratory on that most complicated of all types of discharge—the passage of electricity through a vacuum tube. Anyone who has witnessed the gradual exhaustion of a vacuum tube from atmospheric pressure to the lowest vacuum cannot fail to have been

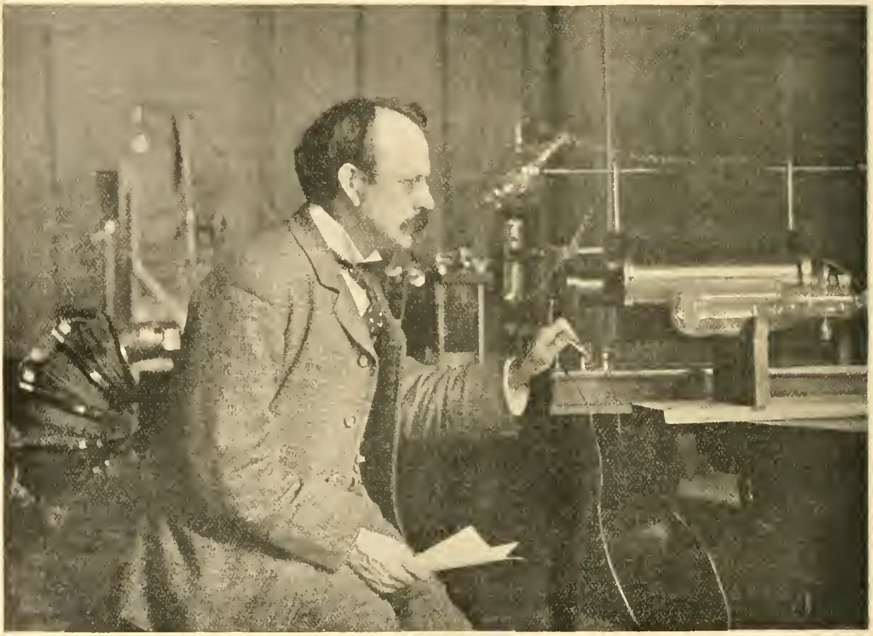

FIG. 1.—Prof. J. J. Thomson in the Laboratory.

e/m, the ratio of the charge on the particle to its mass, was about 1000 times greater than the value of e/m for the hydrogen atom in the electrolysis of water. If the charge is the same for both, this shows that the mass of the kathode ray particle, or corpuscle as it was termed, is only about 1/1000 of the mass of the hydrogen atom. The great penetrating power of the corpuscles and the law of their absorption in matter all supported the idea that the corpuscle was small compared with the molecules of matter. The value of e/m of the corpuscle was found to be independent of the gas in the vacuum tube.

A series of experiments was then undertaken which led to very remarkable results. J. J. Thomson found that the negatively charged particles, released by the action of ultra-violet light on a zinc surface, and from

struck with the variety and complexity of the phenomena displayed by the electric discharge through it. While much work still remains to be done, it may safely be said that the main phenomena are now fairly well understood, and can be satisfactorily explained on the ionisation theory of gases.

In addition to this work on the passage of electricity through gases, J. J. Thomson has also attacked the allied problem of the passage of electricity through metals. A theoretical paper on this subject was contributed by him to the International Scientific Congress at Paris in 1900, in which the negatively charged corpuscles in the metal were considered to be the chief factors in the transmission of electricity. Two possible experimental methods of attack on the question were suggested—the effect of a transverse mag-

netic field on the resistance, and the increase in specific resistance of very thin films. Mr. Patterson, working in the Cavendish Laboratory, has followed out these lines of attack with considerable success. The results obtained were in agreement with the predictions of the theory. While we must await the result of other lines of research for a further knowledge of this important question, a very promising beginning has already been made.

The great mass of work published during the last seven years by J. J. Thomson and those working under him in the Cavendish Laboratory has enormously increased our knowledge of the nature of the electric discharge, and has worked a veritable revolution in ideas of the constitution of matter. When sufficient time has elapsed for the importance of this work, and of the consequences that follow from it, to be more accurately estimated, it is not too much to say that it will be recognised as marking an epoch in the history of physical science.

It is now necessary to speak of a movement for the promotion of research that has been fraught with important consequences to the Cavendish Laboratory and to Cambridge University in general. In 1895 the Universities of Oxford, Cambridge, Edinburgh, and Glasgow arranged to admit graduates from other universities to a course of post-graduate study without any examination or restrictions. These advanced students are allowed at once the position and privileges of the Bachelor of Arts of the university. If the advanced student devotes himself entirely to research under some recognised teacher, he may obtain the degree of B.A. without examination after two years' work, provided the results of the investigation submitted are "of distinction as a record of original research." In practice the standard of this research degree is equivalent to that of the degree of Doctor of Science in most other universities. The result of this wise legislation was at once made manifest. Large numbers of advanced students, not only from the universities of Great Britain, but also from her colonies, from America, and from the Continent, have come to Cambridge to take advantage of her unequalled facilities for advanced work and research. In no department has this influx of advanced students been more numerous or its influence more strongly felt than in the Cavendish Laboratory. Attracted by the genius of the professor, those anxious to pursue research in physical science have come from all parts of the world. The numbers were small at first, but have steadily increased until this year nearly thirty young men have been engaged in research in the Cavendish Laboratory alone. The gathering is a thoroughly cosmopolitan one. Here we find working together graduates not only of most of the universities in Great Britain, but also from Canada and Australasia, from the United States of America, with an occasional representative from France, Germany, and Austria. The mutual influence of such a number of young investigators, each engaged in the pursuit of science for its own sake, cannot be too highly estimated. Unlike some foreign laboratories, there is a thorough freemasonry among the workers in Cambridge. Beside his own research, a student is acquainted with that of twenty others working beside him. He knows their difficulties and the methods of overcoming them, and at the same time is able to see within a short period the cumulative effect of their labours.

The influence towards research exerted by Prof. Thomson on all those who have worked under him is no evanescent one, for his students continue to do good original work and to foster the spirit of investigation, whether they reside in Great Britain or in her colonies. As a sign of their appreciation of the services of J. J. Thomson, the past and present workers in the laboratory have had painted an excellent portrait of the professor, which has just been hung in the laboratory.

The amount of work involved in the superintendence of the researches of so many students is necessarily very great, yet this is undertaken by Prof. Thomson with the utmost willingness and individual interest. Every morning the professor goes the round of the laboratory and inquires of each student the progress of his work. When difficulties arise he is always ready to give the student the benefit of his knowledge and experience, and to make valuable suggestions for future work. In the afternoon there is a social gathering for tea in the professor's room, where he is always ready to discuss scientific matters or to enjoy the latest joke.

Few men are capable of working so steadily and at such high pressure as Prof. Thomson. Besides superintending the teaching and research work of the laboratory and delivering courses of advanced lectures, he is continuously engaged in scientific investigation.

In the preparation of his experiments he is assisted by Mr. Everett, whose skill in glass blowing and manipulation is always kindly placed at the disposal of the laboratory. In addition to a great amount of experimental work, Prof. Thomson, in conjunction with Prof. Poynting, has found time to publish a series of valuable text-books. Two works on sound and properties of matter have already appeared, and a third is in the course of preparation. At the same time, a volume on the discharge of electricity through gases has lately been published. Much of the work has been done by Prof. Thomson and his students in the Cavendish Laboratory, and an account of this important subject is awaited with much interest by physicists.

Prof. Thomson has not confined his energies to England, but has, during his Cambridge vacations, twice visited the United States of America by invitation to deliver courses of lectures. In the first visit he gave a course of lectures at Princeton University which has been published in book form. In his second visit this year, he gave courses of lectures at both Yale and Johns Hopkins Universities. The American physicists are second to none in their admiration of the work done by Prof. Thomson, and his lectures have been attended in great numbers by physicists from all parts of the States. Anyone who has been in America must have been struck by the deep impression created by these lectures.

The large amount of research carried on in the laboratory has not been allowed to interfere to an undue extent with the regular teaching and practical courses. The Cavendish Laboratory was one of the first to appreciate the great importance of practical work in the teaching of science. The excellent laboratory courses now provided for all classes of students are to a large extent due to the labours of Glazebrook, Shaw, Newall, Fitzpatrick, Wilberforce, Skinner, and Searle.

Mr. Fitzpatrick and Mr. Skinner have organised an elementary practical course of instruction for the medical students, while Mr. Searle has devised an admirable course of physical experiments for students taking the first part of the science tripos. The advanced course of practical instruction is at present supervised by Mr. C. T. R. Wilson.

The amount of apparatus required for such a large number of students engaged in research has naturally proved a severe drain on the resources of the laboratory. As in many other scientific laboratories in England, the funds for improving the equipment have been limited. The University of Cambridge has always been liberal in the support of science, but in the present state of the university funds the money to

be allotted to any one laboratory is of necessity small. The Cavendish Laboratory in the past has done most excellent work in somewhat difficult circumstances, but at the present time there is a crying necessity for both increase of space and equipment to carry on the work of the laboratory under the best conditions. Splendidly equipped laboratories are now springing up in all parts of the world, and it is a matter of regret that funds should not be available for the extension and further equipment of the Cavendish Laboratory to keep pace with the times. Under Prof. Thomson, the laboratory has done splendid work in the past, and will continue to do splendid work in the future, but more and better work would be done if greater space and more apparatus were available. An additional sum of 20,000*l.* spent on the laboratory would greatly increase its efficiency, and it would be difficult to find an investment for such a sum which would be productive of such great returns to the cause of science and indirectly to the welfare of the race.

GREAT BENIN.[1]

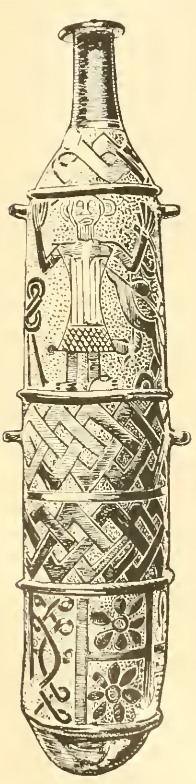

FIG. 1.—Engraved brass bottle, Height 16 in. British Museum. From "Great Benin," by H. Ling Roth.

THOSE who are acquainted with Mr. Roth's earlier meritorious books, "The Tasmanians" and "The Natives of Sarawak and British North Borneo," will know what to expect in a new work by that enthusiastic and indefatigable student. One is impressed with Mr. Roth's evident intention to be quite fair, and to present to his readers all the available data, but the literal quotations from various authors lead to inevitable repetition and occasional contradiction. As in his book on Borneo, Mr. Roth has been at great pains in collecting from scattered sources very numerous interesting illustrations, which materially enhance the value of the book. Mr. Roth appears to have a predilection for issuing limited editions of his books, and we are informed that "the number of copies of this work is limited to 320, and no other or cheaper edition will be issued."

The permanent fame of Benin will rest not on the butcheries of slaves and other unfortunates which shocked the civilised world, but on the skill displayed by the native artists in wood and ivory carving, and more especially by the artificers in bronze and brass. The first castings that came to Europe revealed an unsuspected mastery of technique, and despite the publication of several papers and a couple of memoirs by various students, there is yet more to learn concerning the significance of the very varied subjects represented. Mr. Roth takes a view that differs from that supported by most previous writers; he believes that the art existed in Benin prior to the advent of the Portuguese at the end of the fifteenth century, and that it was just emerging from the stage of realistic representations and beginning to make an attempt in the direction of decoration. As was the case with many other things with which the Portuguese came in contact, these remarkable explorers left their mark strongly impressed on this art work, and thus the natives began that series of borrowed forms which is so mixed up with native motives; perhaps Mr. Roth is somewhat too prone to see exotic designs in Benin art work.

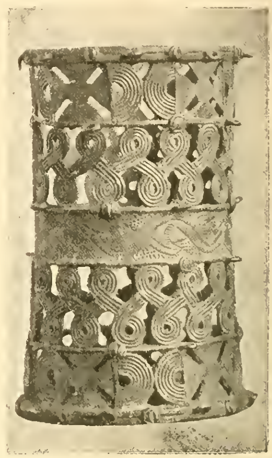

FIG. 2.—Brass armlet, 5¾ in. high In Mr. R. K. Granville's collection. From "Great Benin," by H. Ling Roth.

We reproduce in the first figure a brass bottle with very characteristic interlaced patterns, which are evidently derived from leather-work. The brass armlet or leglet in the second figure has some typical ornamentation; it is said these long armlets or leglets are put on when the individual is quite young, and not taken off until death, if then; in the event of removal, the foot or hand has frequently to be chopped off first.

With so much to choose from, it is difficult to indicate what the book contains; the sociologist will find what is known concerning domestic life, court life, government, trade and industries; the ethnographer is informed about weapons, games, buildings, and what the people do and make.

Mr. Roth's object has been to gather together all he could discover about Benin, and, besides earlier publications, he has drawn largely upon Mr. Cyril Punch, an excellent observer who in addition has furnished Mr. Roth with sketches and interesting photographs. Fresh information has also been given by the author's brother, Dr. Felix N. Roth.

Owing to the number of authors cited, added to the fact that none of them made anything like a study of the people, the information garnered by Mr. Roth is very fragmentary, but the author is not to blame for this, and the book will have further increased its usefulness if it indicates how imperfect our knowledge is, and leads to a more detailed and thorough study of the people. It will, however, always remain a valuable work for students, as references are given with fulness, and it is embellished with a large number of excellent illustrations

[1] "Great Benin, its Customs, Art and Horrors." By H. Ling Roth. Pp. xxxii+234 with 275 illustrations. (Halifax: F. King and Sons, Ltd., 1903.)

THE SURVEY FORMATION-MONOGRAPHS.[1]

Besides the descriptions of districts and the explanations of the published maps and sections, the Geological Survey has of late years issued treatises upon separate formations. In these a full description is given of certain geological horizons the survey of which has been completed or so nearly finished that there is no probability of any important change of classification being called for. The subject is exhaustively treated, the palæontological and petrological characteristics of the group are described, and its relation to the equivalent geological deposits on the Continent discussed. The work before us is the second of three volumes on the Cretaceous rocks. The first volume dealt with the Lower Cretaceous, the second, which has just been published, being devoted to the Lower and Middle Chalk, and the third, which it is hoped will be published this year, completing the monograph with a description of the Upper Chalk, the discussion of some postponed economical and geographical questions, and the full list of Chalk fossils.

The authors are of opinion that none of the lithological names hitherto applied to portions of the Lower Chalk can be used without confusion or inconsistency, and find themselves compelled to seek a more satisfactory method of subdivision in the limitation of the range of certain species of fossils. Nor do they seem to regard with much more favour the use of names derived from localities. We must be careful, however, in the advance towards fuller knowledge of details not to sacrifice precision to consistency. A locality can always be found, and when we get there we can generally see what an author meant. Fossils are not always forthcoming, and from the nature of the case frequently turn up where not found before. Moreover, the names of fossils are being too often changed. Palæontology, in its present phase, is a very useful handmaid in geological classification, but a very exacting mistress in nomenclature. The zone of *Terebratulina gracilis*, for instance, is so called after a form of doubtful determination, unsettled name, and inconstant occurrence.

It is interesting to follow the authors when they point out and explain the changes in the Cretaceous rocks as they trace them from one area to another. In the south-west, coarse sand and grit take the place of chalk, and suggest that we are getting near the shore of the Cretaceous sea, and that newer beds crept over the older deposits which are seen at the base further east, where the land went down first. So Barrois has observed that certain beds in the north-east of France thin out as they approach the Palæozoic ridge, while the Lower Chalk in the south-west is represented, as in the Sarthe, by sands and sandstones. Chemical and mineralogical examination tells the same tale. The fine mud, which in Wilts furnishes 16 per cent. of the material, increases in the deposits of the same horizon as we trace them to the N. and N.E. to 28 or 41 per cent. Minerals which are well known constituents of the granitic rocks of the south-western counties occur in the Lower Chalk of the far south-west, but have not been found in the corresponding beds of the midlands.

Many interesting subjects for investigation are suggested by an examination of the Cretaceous series. The replacement of portions of the chalk by flint might at first seem to require only depression to such a depth that the temperature of the included water would be sufficiently raised to carry silica in solution, while the pressure was so great that the chalk-dissolving acids would be retained in it. But there are other factors of which we must take account. The arresting or retarding of the percolating water had something to do with it, as may be inferred from the manner of occurrence of tuberous and tabular flint along the bedding and joints, and the limitation of flint over large areas to certain horizons so constantly that their abundance or absence was long taken as a sufficient indication of the horizon. So also the supply of silica from spicules in the upper part, or the presence of much siliceous sand in the lower part, must be taken into consideration.

Phosphatic nodules, which occur at widely separated horizons from the Bala Limestone to the Crag, are peculiarly variable in character and mode of occurrence in the Cretaceous series, and from their economic value and scientific interest call for discussion. Some of them are derivative from older beds, and the area from which they have drifted has been pretty clearly made out, but that only pushes the question into other associations; the difficulties remain. There is generally evidence of a change in conditions of deposit where they occur, but it does not often point to a stationary period when animal life was abundant and sedimentation slow, which appear to be the conditions required in explanation.

The name clunch is applied to any chalk which is used as a building stone, whether it is obtained from the firmer beds in the marl, or from the Totternhoe stone or even from higher horizons. Where the Totternhoe stone is accessible it is preferred. It has been largely used at Ely, Burwell, and elsewhere for internal decorative work, and if cared for has often lasted wonderfully, even where exposed to the action of the weather. Near Reach it has been quarried from Roman times, as proved by its having been used in the basement of the Roman villa found near the railway east of the village.

The Red Rock of Hunstanton, &c., does not find a place in this volume, because it was not considered to be part of the Lower Chalk, but was regarded as the representative of the gault, and was accordingly described in the previous volume. Other red beds, however, occurring at higher horizons in the chalk are duly noticed. The Lower Greensand, which is green in borings, is foxy-red or yellow at the outcrop. This is clearly due to the percolation of water from the escarpment. There is much to suggest that the Red Chalk of Hunstanton may have sucked up the colour by capillary attraction from the underlying Car-stone. The red colour does not, however, always coincide with bedding planes, and the irregular occurrence of red beds in the chalk described in this volume is not so easily explained.

The memoir is an able exposition of the results which have been arrived at by long and careful work concentrated upon certain definite geological horizons, but illustrated by wide observation and study. It well supports the prestige of these formation-monographs, from which a large and ever increasing public derives so much benefit.

[1] Memoirs of the Geological Survey of the United Kingdom. The Cretaceous Rocks of Britain. Vol. ii.—The Lower and Middle Chalk of England By A. J. Jukes-Browne, with contributions by Wm. Hill. Pp. xiii+568+plates. (London: H.M. Stationery Office, 1903.)

NOTES.

We regret to announce that Mr. Herbert Spencer died on Tuesday morning, at eighty-three years of age.

The death is announced of Prof. Proust, the French Inspector-General of Sanitary Services.

The ships *Morning* and *Terra Nova* left Hobart on December 6 to go to the relief of the *Discovery*, now in the Antarctic regions.

The Rev. T. R. R. Stebbing, F.R.S., has been elected zoological secretary, and a member of the council, of the Linnean Society in succession to Prof. G. B. Howes, F.R.S., who has had to retire on account of ill-health.

Prof. W. D. Halliburton, F.R.S., has been selected to give the Herter lectures in connection with the University of New York in the coming year, and he has chosen as his subject the biochemistry of muscle and nerve. The lectures will commence on January 4, 1904.

A service in memory of the late Sir Frederick Bramwell, Bart., F.R.S., was held at St. Margaret's Church, Westminster, on Friday last, December 4. The service was attended by a large congregation, which included representatives of the Royal Society, British Association, Institution of Civil Engineers, and many other scientific and technical bodies.

A Dalziel message states that, having successfully exchanged messages regularly between Berlin and Munich, a distance of about 500 miles, the German Wireless Telegraphy Company is about to endeavour to establish communication between Berlin and the Swedish coast near Stockholm, a distance of more than 650 miles. The company uses a combination of the Slaby-Arco and Siemens systems.

Mr. F. F. Francis, Queen's Road, Wimbledon, writes to record an instance of a snake being killed by a mouse. An ordinary grass snake which he had in confinement was given a mouse for food. The snake made several attempts to catch the mouse, but in every case missed. The next day the snake was found to be dead, and there was evidence that it had been attacked and killed by the mouse, which was alive and had eaten a part of the snake's body.

An open competitive examination for not fewer than twenty-four situations as assistant examiner in the Patent Office will be held by the Civil Service Commissioners in January next. The examination will commence on January 5, and forms of application for admission to it will probably be ready for issue in the course of a few days; they will be obtainable on request addressed by letter to the secretary, Civil Service Commission, Burlington Gardens, London, W.

The Aberdeen Line steamer *Sophocles* arrived at Plymouth on December 3 from Sydney after experiencing exceptional weather in the Bay of Biscay. It is reported that during a severe thunderstorm the ship was struck by lightning, and the mainmast was scorched and blackened. A few minutes later, it is said, a brilliant meteor burst in the vicinity of the liner. "The attention of the passengers was attracted by a rushing sound, and immediately afterwards they saw an object plunge into the sea, apparently a few yards distant, on the starboard side of the liner, throwing up the water with a great splash."

Prof. L. C. Miall, F.R.S., has been elected Fullerian professor of physiology at the Royal Institution. The following are among the lecture arrangements at the Institution before Easter:—A Christmas course of lectures (adapted to a juvenile auditory) on extinct animals, by Prof. Ray Lankester; Prof. L. C. Miall, six lectures on the development and transformations of animals; Dr. E. A. Wallis Budge, two lectures on the doctrine of heaven and hell in ancient Egypt, and the books of the underworld; Mr. G. R. M. Murray, three lectures on the flora of the ocean; Mr. A. D. Hall, three lectures on recent research in agriculture; Prof. H. L. Callendar, three lectures on electrical methods of measuring temperature; and six lectures by Lord Rayleigh on the life and works of Stokes. The Friday evening meetings will begin on January 15, when a discourse will be delivered by Lord Rayleigh on shadows; succeeding discourses will probably be given by the Rev. Walter Sidgreaves, Mr. D. G. Hogarth, Mr. H. Brereton Baker, Mr. Alexander Siemens, Prof. W. Stirling, Prof. F. T. Trouton, Prof. Dewar, and other gentlemen.

Mr. W. T. Gibson has been appointed curator of the station of the Marine Biological Association of the West of Scotland, and Mr. J. M'Kenzie has been appointed assistant curator. Mr. Gibson is an associate of the Royal College of Science in London, and received his scientific education there, and also at the University of Edinburgh. He has done marine field work at the Gatty Laboratory, St Andrews, and also at the laboratory of the Northumberland Sea Fisheries Committee at Cullercoats. Mr. M'Kenzie has for the last eight years been laboratory assistant in the zoology and geology departments of Marischal College, Aberdeen.

The International Sanitary Conference, which has been sitting in Paris since October 10, has just closed its proceedings. A modification has been introduced in the period of surveillance in cases of contact with plague; this is reduced from ten to five days. The new convention provides for the manner in which outbreaks of cholera or plague are to be intimated, and, generally speaking, provides for greater facilities for international commerce, while giving additional guarantees for public health. It is proposed that an international sanitary office shall be established in Paris.

In a lecture upon intra-cellular bacterial toxins, delivered at the Lister Institute by Dr. Allan Macfadyen, the method of mechanically grinding bacteria with the aid of liquid air was demonstrated. The lecturer pointed out that there were two classes of bacteria, one, of which diphtheria and tetanus were examples, excreting, as it were, soluble poisons or toxins into the culture medium, the other producing no extra-cellular poisons, and in which the toxins seem to be associated with the bacterial cells, as is the case with tubercle, typhoid, cholera, plague, and a number of others. By disintegrating the cells of the last-named class, the intra-cellular toxins are set free, and on injection into animals produce toxic effects. By cautious injection with these intra-cellular toxins, the blood of the treated animal acquires antitoxic properties, and it is hoped that it may be possible by this means to obtain antitoxic sera for such diseases as typhoid fever and plague, similar to those now employed for diphtheria and tetanus.

Sir Patrick Manson, F.R.S., delivered an address on Monday afternoon at the London School of Tropical Medicine on the work of the school, the occasion being the departure of Sir Francis Lovell, the dean, for the East on behalf of the school. Sir Patrick Manson, having traced the history of the foundation of the school, paid a tribute to the late Colonial Secretary, who has done so much to forward the study of tropical medicine. With regard to the work of the school, it naturally came under two headings—education and research. Since the school was opened in October, 1899, no less than 354 students had passed through its portals. Research had been prosecuted so far as the limited means at their disposal had permitted. Dr. Low had shown that the filaria was introduced into the body by a mosquito, Drs. Low and Sambon had carried out an important experiment to prove the mosquito-malaria theory, Dr. Forde, a pupil of the school, had discovered a trypanosome in man, and Dr. Castellani had observed a trypanosome in sleeping sickness. Through the generosity

of Sir John Craggs a travelling scholarship of 300*l*. a year had been bestowed for three years, and the same donor now gave a valuable prize annually for the best piece of research work carried out by a pupil of the school. The need for further funds was emphasised if the work of the school was to be successful in the future. Sir F. Lovell in a previous mission to the East had collected a considerable sum of money, 100,000 rupees being contributed by the Hon. B. Petit, of Bombay.

The suggestions made by Sir Oliver Lodge at the Physical Society on November 13 (see p. 94) as to the possibility of dissipating fog by discharge of electricity into the air have attracted much attention. Experiments proving how a smoke-filled chamber could be cleared by the discharge were shown by Sir Oliver Lodge twenty years ago, and have been repeated by many lecturers since then, but no installation on a large scale was established. In reply to a correspondent who has asked whether street arc lamps could be utilised for the purpose, Sir Oliver Lodge says, "Your suggestion seems a practical one, and it would be a very good thing if something of that kind could be done. The difficulty is the insulation. If that could be guaranteed, the matter would be comparatively easy; but the potential is extremely high—say 100,000 volts. The quantity is next to nothing, and very little power is sufficient if only one could avoid leakage. I can tell you the kind of insulators that we employed for the single mast that I used in Liverpool, but it is a very different thing to try to distribute it over a number of street lamps. It is a matter very well worth consideration, however, and I am glad to find that your attention is called to the matter. In the Liverpool experiment I was using a potential higher than 100,000 volts; one could take sparks 4 inches long. But a good deal smaller voltage would do if there are walls or other earthed surfaces in the neighbourhood. For a lofty isolated mast the potential must be higher in order to secure adequate discharge."

At the meeting of the Institution of Civil Engineers on November 24, Dr. H. R. Mill read an interesting paper on the distribution of mean and extreme annual rainfall over the British Isles. The results, which were exhibited by isohyetal lines, or lines of equal rainfall, were based on the means of thirty years, 1870 to 1899, and showed that a mean annual fall under 25 inches occurs in three places:—(1) a very narrow strip round the Moray Firth; (2) a triangular area about the Thames estuary; and (3) a large portion of east central England south of the Humber; and that the amount increases in various districts, in which altitude and configuration of the land form important features, to 40 inches and upwards. Falls of more than 100 inches are found:—(1) in the lake district, around Seathwaite; (2) in the western Highlands; and (3) in the Snowdon district. The average rainfall, to the nearest half-inch, for each country is given as follows:—England 31·5, Wales 49·5, Scotland 47·0, Ireland 42·0 inches, and for the whole of the British Isles 39·5 inches. The extremes of annual rainfall were discussed by taking out the figures for the driest and wettest year of the thirty years' period. The excess of rainfall in 1872 was stated to be 34 per cent., and the deficiency in 1887 23 per cent. of the average fall for the British Isles as a whole. The average rainfall over the whole of the British Isles for these two years was:—in 1872 53 inches, and in 1887 30·5 inches.

We have received a prospectus of a new fortnightly meteorological bulletin, entitled *La Previsione del Tempo*, to be published in Rome on the 1st and 16th of each month, under the superintendence of Father A. Rodriguez. The bulletin will consist of eight large octavo pages, four of which will be occupied by diagrams exhibiting the principal meteorological data, and will form the basis for the calculation of the proposed predictions. These data will refer to some of the chief places in Europe (including Ireland), Algeria, and Tunis, for each of which forecasts are to be drawn. The remaining four pages will consist of text, and will contain a brief summary of the atmospheric changes of the preceding period, forecasts for the succeeding period, meteorological notes, and the fundamental principles of the system of prediction employed. The author has set himself a difficult, and we fear an impracticable, task, but as he apparently proposes to proceed upon strictly scientific lines, we shall be interested to learn what amount of success he may obtain. For this country at least, the changes from one type of weather to another appear to be too sudden to allow of a tolerably safe forecast for more than a day or two in advance, nor has more been yet attempted by any of the European central meteorological offices. The author, however, appears to be sanguine of obtaining a success of 65 to 75 per cent.

In the Meteorological Office pilot chart for December the attention of mariners is directed, in a lengthy description of the Aurora Borealis, to the question of more careful and systematic observations of the various phases of auroræ. They are asked to supply details as to the following points, to which scientific inquiry might be directed:—The angle which the apex of the arch makes with the horizon; the orientation of the arch or arches; the lateral motion of the streamers, whether from right to left or left to right: does the individual streamer move sideways, or do fresh streamers arise to one side of the former? As a rule, streamers are parallel to the dipping needle—it should be noted if any streamers are curved. Can stars be seen immediately under the base of streamers? It should be noticed if the arches always move from north (magnetic) to south, and, if so, whether it is by a motion southward of the individual streamers or by new streamers appearing to the south of the old ones; the formation of coronæ by streamers should be carefully watched and noted, and special notice should be taken of the behaviour of the compass when an aurora presents the appearance of a luminous curtain.

A short account of the meeting of the Deutsche Gesellschaft für Mechanik und Optik which took place at Ilmenau on August 14 and 15 is given by Prof. L. Ambronn in the *Physikalische Zeitschrift* for November 15.

The *Verhandlungen* of the Deutschen zoologischen Gesellschaft for the present year contains the papers read at the session held in Würzburg on June 2–4. In the obituary notices reference is made to the loss sustained by zoological science in the death of Prof. G. Radde, of Tiflis. The papers, which are for the most part short, cover a wide range of subjects, but there are none among them which call for special notice.

We have received a copy of Prof. W. B. Benham's presidential address to the biological section of the Australian Association. The subject is the geographical distribution of earth-worms and the palæography of the Antarctic region. In the first place, from their invariable association with angiospermous plants, the author is of opinion that earth-worms form a comparatively modern group, which did not attain any important development before the Cretaceous. The ancestral type would appear to have been more or less nearly related to the existing Notiodrilus, of which the headquarters, if not the birthplace, was the "Melanesian plateau." New Zealand and the neighbour-

ing islands, which possess the most ancient worm-fauna, were separated at an early date from this plateau. From this area the primitive worms travelled in one direction into the Austro-Malayan countries, while in another, by way of Antarctica, they reached South America and Africa. Other theories as to former land-connections in the southern hemisphere are propounded.

In the *Transactions* of the South African Philosophical Society Dr. Bolas and Major Wolley-Dod have published a list of the flowering plants and ferns of the Cape Peninsula, and have thereby brought to notice a flora which presents a number of unique features. In the first place, from an area of rather less than 200 square miles, they report more than 2000 flowering plants, and amongst these there are a number of representatives of such uncommon orders as Selaginaceæ, Restiaceæ, and Proteaceæ. Another striking character is the richness in species of several genera; thus Erica possesses no fewer than 92 species, Mesembryanthemum shows 61, while the very rare genus Restio has as many as 29 representatives.

Much uncertainty has existed as to whether or no the bacterial cell possesses a nucleus. Some have considered that it does not, others that it contains a fragmented one, or one of the ordinary type, or that the whole cell is a naked nucleus. Profs. Rayman and Kruis (*Bulletin* Acad. des Sciences de l'Empereur François Joseph I., June 5) claim to have shown by a special staining method that a nucleus is present in the form of a small round body situated at about the centre of the cell. In order to demonstrate this structure, films are prepared on perfectly clean cover glasses, dried in a desiccator, treated with a mordant of iron-alum, and stained with a dye known as alizarine PS, or its constituents. The paper is illustrated with some excellent reproductions of photographs.

We have received the *Transactions* of the Leicester Literary and Philosophical Society for the session 1902–3. The volume also contains the report of the council and the annual reports of the sections into which the Society is divided for working purposes. Numerous papers are reprinted, and some of them are well illustrated. The volume is published at sixpence by Messrs. Thornley and Waddington, of Leicester.

A third edition of Prof. James Walker's "Introduction to Physical Chemistry" has been published by Messrs. Macmillan and Co., Ltd. A new chapter on electromotive force has been added, and the chapter on thermodynamical proofs has been extended. In cases where recent researches have made it possible, more accurate numerical values and better illustrative examples have been substituted in the text.

The current number of the *Quarterly Journal* of the Royal Meteorological Society is an interesting one. Dr. W. N. Shaw, F.R.S., in a paper containing several instructive figures, gives a detailed analysis of the meteorological aspects of the storm of February 26–27. Mr. C. P. Hooker discusses the relation of the rainfall to the depth of water in a well; Mr. W. Marriott examines the available observations in connection with the frost of April, and Mr. J. Baxendell gives illustrated descriptions of the Dines-Baxendell anemograph and the dial-pattern non-oscillating pressure-plate anemometer.

It is now the common practice to illustrate lectures and demonstrations in most schools and colleges by means of the lantern and lantern-slides. Those teachers and lecturers who have not mastered the art of making their own slides would do well to study the lists of slides which are to be purchased from Messrs. Newton and Co., of Fleet Street, London. We have received from this firm a supplementary list of slides to illustrate scientific and other subjects, and among them we notice sets dealing with the growth, structure, and defects of timber; the evolution of a frog; the bacteriology of tropical diseases; and the open-air cure for consumption.

A new illustrated catalogue of chemical apparatus recently published by Messrs. F. E. Becker and Co., of Hatton Wall, London, is one of the most complete and conveniently arranged that we have examined. Every item in the list is illustrated by a figure immediately adjoining it, and the unusually full index makes reference very easy. The catalogue gives information concerning all forms of chemical apparatus in general use in laboratories, and an exhaustive list of chemicals, reagents, and standard solutions is also included. Teachers of chemistry, and those who are engaged in chemical research, should obtain a copy of the catalogue to keep in their laboratories for reference.

A translation of a long thesis on radio-active substances, presented to the Faculté des Sciences de Paris by Mdme. S. Curie, is concluded in the current number of the *Chemical News* (December 4). The conclusions read as follows:—"I will define, in conclusion, the part I have personally taken in the researches upon radio-active bodies. I have investigated the radio-activity of uranium compounds. I have examined other bodies for the existence of radio-activity, and found the property to be possessed by thorium compounds. I have made clear the atomic character of the radio-activity of the compounds of uranium and thorium. I have conducted a research upon radio-active substances other than uranium and thorium. To this end I investigated a large number of substances by an accurate electrometric method, and I discovered that certain minerals possess activity which is not to be accounted for by their content of uranium and thorium. From this I concluded that these minerals must contain a radio-active body different from uranium and thorium, and more strongly radio-active than the latter metals. In conjunction with M. Curie, and subsequently with MM. Curie and Bémont, I was able to extract from pitch-blende two strongly radio-active bodies—polonium and radium. I have been continuously engaged upon the chemical examination and preparation of these substances. I effected the fractionations necessary to the concentration of radium, and I succeeded in isolating pure radium chloride. Concurrently with this work, I made several atomic weight determinations with a very small quantity of material, and was finally able to determine the atomic weight of radium with a very fair degree of accuracy. The work has proved *that radium is a new chemical element*. Thus the new method of investigating new chemical elements, established by M. Curie and myself, based upon radio-activity, is fully justified. I have investigated the law of absorption of polonium rays, and of the absorbable rays of radium, and have demonstrated that this law of absorption is peculiar and different from the known laws of other radiations. I have investigated the variation of activity of radium salts, the effect of solution and of heating, and the renewal of activity with time, after solution or after heating. In conjunction with M. Curie, I have examined different effects produced by the new radio-active substances (electric, photographic, fluorescent, luminous, colorations, &c.). In conjunction with M. Curie, I have established the

fact that radium gives rise to rays charged with negative electricity. Our researches upon the new radio-active bodies have given rise to a scientific movement, and have been the starting point of numerous researches in connection with new radio-active substances, and with the investigation of the radiation of the known radio-active bodies."

The additions to the Zoological Society's Gardens during the past week include two Black-eared Marmosets (*Hapale penicillata*) from South-east Brazil, presented by Mr. J. Arthur Turner; a Short-toed Eagle (*Circaëtus gallicus*) captured at sea, presented by Lieut. W. H. Colegrave, R.N.R.; four Chameleons (*Chamoeleon vulgaris*) from North Africa, presented by Mr. Thomas Yates; a Vervet Monkey (*Cercopithecus lalondii*) from South Africa, two Slender Loris (*Loris gracilis*) from Ceylon, a Blue-fronted Amazon (*Chrysotis aestiva*), a Rough-eyed Cayman (*Caiman sclerops*), five Black-pointed Teguexins (*Tupinambis nigropunctatus*) from South America, a Red-billed Toucan (*Ramphastos erythrorhynchus*) from Cayenne, two Red-handed Tamarins (*Midas rufimanus*) from Surinam, a One-bearded Greaved Tortoise (*Podicnemis unifilis*) from the Upper Amazons, deposited.

OUR ASTRONOMICAL COLUMN.

Observations of Solar Phenomena.—In a paper presented to the Paris Académie des Sciences, M. Deslandres discusses the various theories concerning the inter-relation of solar and magnetic phenomena which have been brought into prominence by the exceptional magnetic storm of October 31. He points out that, whereas the magnetic phenomena are recorded continuously at many widely separated observatories, the solar observations, which constitute the other side of the problem under discussion, are only made during short intervals each day and at fewer stations; therefore he strongly urges that solar observatories should be more widely disseminated in order that a *continuous* record may be obtained. Again, he points out that, at present, at least ninety-nine out of every hundred observers of the sun only record the *forms*, and not the *movements*, or velocities, of the solar disturbances, whereas in his opinion the records of the latter would prove much more effective in bringing us to a solution of the vexed questions.

M. Deslandres suggested in 1893, and in the present paper he strongly emphasises the fact, that it is essential, in order that our knowledge of solar disturbances may be rendered less defective, to obtain a *continuous* record of :—(1) The surface of the photosphere as photographed by the ordinary process; (2) the *forms* of the disturbances in the lower, mean, and higher chromosphere as obtained with the spectroheliograph; and (3) the radial velocities of these chromospheric disturbances as shown on photographs obtained with the spectroheliograph especially arranged to register these velocities. He states that the present instruments are perfect enough to ensure success, and estimates the annual expense of such observations (at Meudon) as twenty thousand francs (about 800*l.*) (*Comptes rendus*, No. 21, November 23).

The Spectrum of Lightning.—Mr. Phillip Fox, of the Yerkes Observatory, has recently succeeded in obtaining several spectra of lightning flashes which were taken with an objective-prism spectroscope consisting of a 30° flint glass prism mounted in front of a camera of 35 mm. aperture and 274 mm. focal length. Proceeding on the lines suggested by the visual observations of Vogel, Lohse, and Schuster, he compared his spectra with a spark spectrum of air obtained with the same instrument, and found that a striking agreement existed between the two.

Similar results were arrived at by Dr. W. J. S. Lockyer, who, in a recent number of the *Illustrated Scientific News* (No. 15, vol. ii.), described an extremely simple method whereby photographs of lightning flashes and their spectra can be obtained by using an ordinary camera having one of Thorpe's transmission gratings fixed in front of the lens. The spectra thus obtained by Dr. Lockyer in May of this year are shown to differ from those obtained by Prof. Pickering at Harvard in 1901, and a spectrum recently obtained by the latter is again different from either of the other two; all, however, bear a striking resemblance, in general appearance, to the air spark spectrum, the chief nitrogen lines being especially prominent.

In Mr. Fox's spectra it is seen that the various lines differ in intensity from one part of the flash to another, and, as this apparently indicates a variation of the spectrum with the atmospheric conditions, it seems probable that the differences existing between the several spectra may be thus explained.

Mr. Fox's article is illustrated by reproductions of the spectra obtained by him, and a comparison of the air and lightning spectra, and is published in No. 4, vol. xviii., of the *Astrophysical Journal*.

The Line Spectra of the Alkaline Metals.—In No. 27 of the *Physikalische Zeitschrift* Herren H. Konen and A. Hagenbach record the results of some observations made by them with the object of discovering additional lines in the secondary series of the spectra of lithium, potassium, cæsium, and rubidium.

In the spectrum of lithium four new lines were observed, but their diffuse character renders the determined wavelengths (6240·8, 4636·14, 4149·1, and 3934) rather untrustworthy, and for this reason it is difficult to determine finally whether they belong to a definite series or not, although it seems likely, from their character and their analogy to the lines in the sodium series, that they are really pairs, and belong to the first secondary series. No new lines were discovered in the potassium spectrum. In the spectrum of rubidium three new lines were discovered, and fourteen of the fifteen lines observed by Mr. Hugh Ramage in the flame spectrum were seen, although these observers were unable to find, either in the arc or the flame, the line at λ 5037 recorded by Mr. Ramage. These new lines fill up gaps in the first secondary series as calculated from Kayser and Runge's formula.

All the lines recorded by Mr. Ramage below λ 5750 in the cæsium spectrum were observed, together with an additional line at λ 5209.

PATAGONIAN "DIPROTODONT" MAMMALS.[1]

Señor Ameghino appears to be firmly convinced that the ancestors of a large number of groups of mammals are to be met with among the remains from the Santa Cruz and associated beds of Patagonia. Last year, in the journal quoted below, he attempted to prove the descent of the modern elephant, through Pyrotherium and certain other forms, from a primitive opossum (Proteodidelphys). Now he essays to demonstrate that the rodents have originated from another type of Patagonian "diprotodonts," namely, the Garzoniidæ, which is itself traced back to a still earlier group, the Microbiotheriidæ. Apart from zoological considerations, the possibility of such phylogenies depends entirely on the age assigned to the Santa Cruz and subjacent strata. If, with Dr. Ameghino, we regard them as of early Eocene, Cretaceous, and possibly Upper Jurassic age, then, from this point of view, there is nothing impossible in such pedigrees. If, on the other hand, we accept the view of the great majority of palæontologists that these strata are of Miocene age, the very foundations of Dr. Ameghino's elaborate phylogenies are at once destroyed.

Putting, however, this consideration on one side, we may refer briefly to some of the zoological features in the paper before us. Briefly stated, Dr. Ameghino's views, so far as we can follow them, appear to be as follows. In the Upper Jurassic of Patagonia there existed a primitive group of "diprotodonts" (that is to say, mammals furnished with a single pair of chisel-like incisors in the lower jaw), the Microbiotheriidæ. On the one hand, as we learn from the earlier paper, these gave rise to the Proboscidea, while on the other they culminated in the modern rodents, the diprotodont marsupials of Australia, and certain extinct forms,

[1] F. Ameghino, "Los Diprotodontes del ordren des los Plagiaulacoideos y el Origen de los Roedores y de los Polymastodontes" (*An. Mus. Nac. Buenos Aires*, vol. ix., pp. 81–192)

such as Plagiaulax of the Purbeck and Microlestes of the Trias (!). The author appears, indeed, to consider that, with the exception of Pyrotherium (which, despite its remarkable resemblance to Diprotodon, he places in the proboscidean line), all mammals with a diprotodont type of dentition are related to one another. And he endeavours to show that the dentition of one type passes by imperceptible degrees into that of another. But such gradations may be traced between the dentition of almost any groups, and no allowance whatever is made for parallelism in development, which has undoubtedly been an important factor in evolution. Moreover, no account whatever is taken of the undoubted resemblance existing between the cheek-teeth of the polymastodonts and the reptilian Tritylodon.

Then, again, according to the author's scheme, the true diprotodonts of Australia have no relationship with the polyprotodont marsupials of the same region, which is, on the face of it, an absurdity. It may also be pointed out that Dr. Ameghino takes no account of the work of other palæontologists. It is very generally accepted, for instance, that an intimate relationship exists between marsupials (as a whole) with the extinct creodonts, and so with the modern Carnivora (see Wortman, *Amer. J. Sci.*, vol. xiv., 144, 1902), while Prof. Osborn (*Bull. Amer. Mus.*, xvi. p. 203, 1902) has indicated the probability of the descent of the rodents from the Holarctic Eocene Mixodectidæ. Obviously both these phylogenies must be demonstrated false before there is even a *primâ facie* possibility for Dr. Ameghino's scheme. It will be interesting to learn what the United States palæontologists have to say on the subject when the groups in question come to be treated in the working out of the Hatcher collection. R. L.

GEOLOGICAL NOTES.

OBSERVATIONS have been made by Mr. R. D. Oldham on the growth of sandhills, which threaten to cut off communication between the town of Karachi and the suburb of Clifton, two or three miles distant (*Mem.* Geol. Surv. India, xxxiv., part iii.). He traces out the growth of dunes from small oval patches of sand which begin to accumulate on irregular tracts of the stony surface, pointing out that even a slight accumulation may cause an upward bend of the air currents whereby a space of comparative calm is produced, and sand more readily comes to rest. In course of time the oval patches of sand are heaped up with a sharper slope to leeward, down which the sand grains fall. Here a hollow is produced by an eddy of the wind, and this eddy serves to maintain and increase a crescentic form with a crater-like opening. The principal winds at Clifton blow from W.S.W., and form the main features in the sandhills; but winds from the E.N.E. blow during the winter months, causing a reverse slope and a bank of sand to be formed near the summit of the long gentle slope which faces the W.S.W. winds. There is a good deal of scour of the original steep leeward slope, but no complete reversal of the shape of the sandhill.

FIG. 1.—Sandhill near Clifton, Karachi, showing change of form and scour by wind.

Mr. Oldham points out that the original hollow is well shown in the accompanying view. The sandhill was first shaped by W.S.W. winds, then a period of E.N.E. winds caused a partial modification of form, heaping up the sand from that side and producing the steep slope facing to left of the picture. The sandhill was afterwards attacked by a S.W. wind, which commenced to reshape it, and this alteration at first led to the formation of notches in the crest, in which the wind became concentrated, leading to a violent scour and to the excavation of deep pits to leeward. The furthest of the notches has been cut down nearly to the foot of the steep slope. Eventually it and the other notches will be widened, and the intervening pinnacles will be lowered until the crest is reduced to a smoothly rounded outline. Mr. Oldham discusses the means which may be taken to arrest the progress of the sandhills, and concludes that much may be done by encouraging the growth of local grasses.

In an essay on the deformation of rocks, Mr. E. H. L. Schwarz (*Trans.* S. African Phil. Soc., xiv., part iv.) discusses their crushing strength, and remarks that this is less when the specimen tested is soaked in water. In natural circumstances in the earth's crust the crushing value of a column of rock, which would crush the layer at its foot, must be estimated by the weight of the material in water, and the author calculates that a column of sandstone must be from about two-thirds of a mile to five miles in height, one of granite from four to seven and a half miles, and one of felsite from seven to nine miles. The actual zone of mass deformation seems to be much nearer the surface, judging by the "creep" in mine-levels, and by the fact, in the case of deep bore-holes, that a cylinder of rock gradually rises from the bottom. The author alludes to the effect that crushing would produce along the bases of deep gorges, and he points out that the line of inquiry indicates that there must be a limit to the height of mountains and to the thickness of ice-sheets. He further discusses the deformation of rocks at great depths by the action of water.

In the *Proceedings* of the Royal Society of Victoria (n.s. vol. xvi. part i.), Mr. F. Chapman describes some new species of Silurian Polyzoa and Brachiopoda. Prof. J. W. Gregory discusses the formation of the Henty peneplain in N.W. Tasmania. In places it is 1300 feet or more above the sea, but is lower towards the north, west, and south. It appears to have been due to river-action in pre-Glacial times, when western Tasmania stood a few hundred feet lower than it does now. Its comparatively recent uplift is shown by the King River, which, east of Mount Lyell, flows through a very ancient flat-floored valley, and then traverses the peneplain in a sinuous narrow canyon.

An elaborate memoir on the Jurassic Trigoniæ of Cutch has been contributed by Dr. F. L. Kitchin to the *Memoirs* of the Geological Survey of India (Pal. Ind., ser. ix., vol. iii., part ii., No. 1). Most of the species of Trigonia have been obtained from the Putchum-Charee series, which, on the evidence of Cephalopoda, has been grouped with the European Bathonian, Callovian, and Oxfordian strata. In no case has Dr. Kitchin been able to identify any of the Cutch Trigoniæ with European species, but while they afford no definite evidence of the correlation above mentioned, they present no obstacles to its acceptance. They flourished in a different zoological province, but the Lower Charee (Callovian) forms bear the imprint of a facies which characterised a slightly earlier age in Europe, a fact suggestive of migration into the Cutch area. No Trigoniæ have been obtained from the Katrol (Kimeridgian) strata, but in the overlying Oomia beds, which appear to be transitional between Jurassic and Cretaceous, there are Trigoniæ that approximate in adult characters to forms found in the Uitenhage strata of South Africa. There is other evidence which suggests community between the Jura-Cretaceous faunas of the two areas, but as the forms in question differ widely in their youthful characters, Dr. Kitchin regards them as indicating homœomorphous derivation from separate stocks. Evolution of this character may have taken place under similar conditions, but it does not imply contemporaneity. The subject is of great im-

portance in the comparison of forms, in the naming of species, and in the correlation of strata by their aid. As the author points out, it demonstrates the necessity for abundant material in palæontological studies.

Mr. W. H. Dall has published a summary of the geological results of the study of the Tertiary fauna of Florida, 1886–1903 (*Trans.* Wagner Inst. Sci., Philad., iii., part vi.). He points out the objections to the method of grouping which was based by Lyell and Deshayes on the percentage of species that survive to the present day, as the conditions may be more favourable for the survival of species in one region than in another. The presence or absence of identical species in the Tertiary beds on either side of the Atlantic may be an important factor in correlation, but while this is partially true of older geological horizons, yet after the Mesozoic epoch the faunal characteristics of the shallow-water Mollusca of different regions became rapidly distinctive. Even in the Eocene but two or three species can be claimed as identical on both shores of the Atlantic, and in later periods it would be unreasonable to expect to find a series of identical species in subtropical marine invertebrate faunas in widely separated regions. In order to establish correlation, we should look for equivalent stages of evolution in relation to preceding and subsequent faunas, and not expect a greater number of identical species than are found in the contemporaneous faunas of distant areas at the present day. Mr. Dall adopts the grouping of Eogene to include Eocene and Oligocene, and Neogene to include Miocene and Pliocene, and he gives detailed lists of fossils. He discusses the physical changes that have taken place, and agrees that no discontinuity of the link between N. and S. America from the Miocene to the present time is probable, and certainly none amounting to a free communication between the two oceans.

A pamphlet on "Rock Phosphates and Other Mineral Fertilisers" has been issued by Dr. Charles Chewings (C. E. Bristow, Adelaide, S. Australia). The object is to give descriptions of the deposits from which mineral fertilisers originate, with notes on the preparation of the phosphate for the market, as an aid to the prospector and to others engaged in the practical applications of the manures. Particulars are given of phosphate deposits in all parts of the world, but special reference is made to those of Clinton, on Yorke's Peninsula, in South Australia. Here a range of hills, formed mainly of Cambrian rocks, rises to an elevation of nearly 400 feet, and beneath the crest, in a N.E. and S.W. direction, the rock phosphate occurs. It extends for more than 104 chains, varies in width from 8 to 20 chains, and is covered to a considerable extent by alluvial deposits. No fossils have been found in the deposit, and the author gives reasons for believing it to have been derived from guano. Selected samples can hardly be distinguished from the phosphate rock of Christmas Island.

According to Mr. E. O. Hovey (*Science*, November 13) the ascending obelisk of Mont Pelée, of which we reproduced an illustration from a photograph taken on June 13 (NATURE, October 1), has since disappeared. Meanwhile, the dome of the cone surmounting the crater has been greatly altered, and a small spine issued from it early in September. This was pushed up 20 metres within a week, and then destroyed by an eruption. Eruptions giving rise to great dust clouds led to the expectation that further serious disturbances might take place. The latest bulletins (October 1 to 19), however, indicate only feeble activity of the volcano.

We have received the subject list of works on the mineral industries and allied sciences in the Library of the Patent Office. This is a helpful guide to the literature of various subjects, and these are arranged under headings of which assaying, clay and clay industries, coal and coal mining, geology descriptive and applied, lead, limestone, peat, uranium and zinc may be taken as examples. The list is, of course, confined to the works in the Patent Office, and it contains titles of a few books and pamphlets that are worthless from a practical point of view, such as "King Coal's Levee" (1820). Institutions should have authority to part with works of this kind, so that they might be placed in appropriate libraries. The practical utility of the list is, however, great, and the price is only 6*d*.

Some Jurassic fossils from Borneo have been described by Mr. R. Bullen Newton (*Proc.* Malacol. Soc., v., October). These include a new species of Trigonia (*T. Molengraaffi*), the genus being recorded for the first time from the rocks of Borneo. The characters of the fossils indicate that the strata belong to the Lower Oolites.

In some notes on the origin of coral reefs (*Amer. Journ. Sci.*, September) Mr. J. Stanley Gardiner remarks that while some reefs may possibly owe their existence to the subsidence of the land round which they originally formed only a fringe, yet the facts collected during recent years prove that such a method of formation was rare and exceptional. Referring to the Maldive group, he shows that a study of the reefs indicates the following stages:—(1) a basis of primitive rock cut down by the action of currents, &c., and lying at a depth of about 200 fathoms in a sea of more than 2000 fathoms; (2) upgrowth of a shoal by means of deep-sea corals assisted by other organisms; (3) outward extension of the reef by means of detritus; (4) surface reef formed by corals, &c.; (5) land, formed by piling up of sand and rubble on the reef; and (6) lagoon, formed partially by the more rapid growth of the organisms on the edge of the original bank, building up an encircling reef, and partially by the solution and erosion of the central parts.

BIOLOGICAL TREATMENT OF SEWAGE.

FOR some years a very interesting series of experiments in connection with the biological method of sewage treatment has been carried on by Dr. Dunbar, director of the Hygienisches Institut at Hamburg, and by his colleagues. Special attention has been directed to the elucidation of the sequence of changes which underlies the purification process in contact beds and percolating filters.

The most recent conclusions are given in a paper read by Dr. Dunbar at the International Congress of Hygiene and Demography at Brussels, and in several papers in the *Gesundheits-Ingenieur*, more especially in one by Messrs. Kattein and Lübbert in No. 25 of that journal. Great importance is attached by the Hamburg workers to the *rôle* played by the process of so-called "absorption" which takes place when the liquid is in contact with the purifying medium. It has been found that sterile clinkers have the power of withdrawing from solution not only colouring matters, but also the highly complex nitrogenous bodies found in sewage.

The exact meaning to be given to the term absorption is carefully discussed by Kattein and Lübbert in their paper, with copious references to the literature of the subject. It is defined as a purely surface action independent of chemical attraction, analogous, in fact, to the condensation of carbonic acid on glass threads observed by Bunsen.

The purification of the sewage by the ordinary biological methods is considered, in the first place, to be due to the "absorption" by the medium of the putrefactive matters in solution, which are afterwards oxidised through the intervention of micro-organisms. Without the activity of the organisms in presence of oxygen, absorption soon ceases.

The absorptive effect increases with the surface exposed, *i.e* with the fineness of the material. Very considerable reduction of impurities can be effected by a contact of a few minutes, and the effect practically attains its maximum in from four to six hours.

Besides the destruction of the absorbed organic matter, which is due to micro-organisms, some oxidation is effected directly by the atmospheric oxygen, which is also absorbed, and which is shown to be in a specially active condition, as it is capable of instantly oxidising hypochlorites to chlorates, and, more remarkable still, of converting dimethyl-aniline into methyl-violet. The last change can only be brought about in the ordinary way by heating with chlorate, or other powerful oxidising agent.

An interesting example of absorption is seen in the case of the percolating filter adopted by Dr. Dunbar. This filter is provided with a layer of fine material on the surface, about six inches deep. According to Dr. Dunbar, 50 per cent. of the purification, apart from nitrification, takes place in this six inches.

THE ORIENTATION OF THE ANCIENT CHURCHES OF IRELAND.[1]

PROF. J. P. O'REILLY'S paper, although mainly antiquarian, presents certain points of scientific interest worth attention for their novelty and possible application elsewhere. The two churches in question are easily accessible from Dublin, but they have not been fully and sufficiently examined. The author examines what is known of the saint to whom both the churches are said to be dedicated, giving citations from the public records relative to the saint's name and its various forms. He shows that there are at least four different saints of the name of Begga mentioned having different festival days, and points out the admitted uncertainty existing as to the dedicatory saint in question. As a solution, he takes into account the orientation of Dalkey Town Church, assuming that the church was oriented to the rising sun of the saint's festival day. The older or western part of the church is oriented E. 8° 10′ N., while the newer or eastern part or chancel has that of E. 9° 30′ N. He finds the sun to present a northing corresponding to these figures between April 11 and 15 on his passage northward, and between August 29 and *September* 2 on his passage southwards. "As regards," he says, "the festivals of saints mentioned as occurring between August 29 and September 2, the nearest in date would be that of St. Bega (September 3) (the saint venerated at Dunbar)." Hence he draws the conclusion that she was the particular St. Bega to whom the church was dedicated.

Prof. O'Reilly then considers the church on Dalkey Island, points out its remarkable position, gives the details of its structure, and argues that the belfry (so called) was most probably used as an observatory for the determination of the equinox in particular, and for the observation of the stars so as to fix the hours of service. This argument he supports by several citations and a description of the meridian line, with inscriptions, existing in St. Sulpice Church, Paris. He then compares the south-east window now existing in the Dalkey Island church with that of Dalkey Town Church, and shows their close relation in certain respects. This leads to a detailed examination of the south-east opening of Dalkey Town Church, its dimensions and probable use, for the determination of the saints' festival day by the stoppage of the sunlight rays through it at certain times of the year. He shows that this would happen for one of the compartments of the window on April 9 and *September* 4, so that here again the festival day of St. Bega of Dunbar is pointed out. As regards the orientation of Dalkey Island church, he shows that it is about E. 3° south, not due east. He explains this error from the nature of the ground as previously described, and further points out how the true east and west line is given, and was apparently fixed, by a line passing through a Greek cross carved on a rock opposite the western door, and the north-west angle of the church. Lastly, his measures having been made metrically, he finds that the unit of measurement used in the building was the Spanish "Vara" = 0·835m., and gives proofs of this. He thus raises the broad and interesting question of the unit or units of measurement having been in use in Ireland previous to the adoption of the British standard of feet and inches, and invites further investigation in this respect.

[1] "Notes on the Orientations and Certain Architectural details of the Old Churches of Dalkey Town and Dalkey Island, Dublin." By Prof. Jos. P. O'Reilly. Abstract of paper read before the Royal Irish Academy, February 23.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. W. H. Young, Peterhouse, has been approved for the degree of Doctor of Science.

A vacancy for a university lecturer in histology has been caused by the election of Dr. Langley to the chair of physiology. The appointment will be made in the Lent term, 1904.

Dr. Dickinson, Dr. Rolleston, and Dr. Kellock have been appointed additional examiners for medical degrees on account of the large number of candidates in the present term.

The Walsingham medal for biology has not been awarded this year

The Sheepshanks astronomical exhibition is awarded to Mr. P. E. Marrack, one of the senior wranglers of the year.

The observatory syndicate proposes that the office of assistant director of the observatory should be conferred on Mr. H. F. Newall, who has been observer since 1890, without stipend.

The graces for the organisation of the school of geography were opposed in the Senate on December 5, but were carried by large majorities. A board of studies, a special examination for the ordinary B.A. degree, and a diploma in geography are thereby established.

SIR WILLIAM MATHER will distribute the prizes at the Merchant Venturers' Technical College, Bristol, on Thursday, December 17.

A GIFT of 50,000*l*. has been made by an anonymous donor to University College, London, through Prof. Starling, to be used by the council of the college for the promotion of higher scientific education and research at that institution.

MR. JOHN D. ROCKEFELLER has, we learn from *Science*, offered to give Vassar College 40,000*l*., or such part of this sum as may be equalled by gifts from other sources before June, 1904. 10,000*l*. has so far been subscribed, and an appeal is made for further gifts.

THE annual meeting of the Association of Technical Institutions will be held at the Leathersellers' Hall, London, on Friday, January 29, 1904. Sir John Wolfe Barry, K.C.B., F.R.S., will occupy the chair, and an address will be given by the president-elect, the Right Hon. Sir John E. Gorst, K.C., M.P.

IT is announced from New York that the committee to control the selection for the Rhodes scholarships available for Americans has been formed. The presidents of Yale and Harvard Universities are the principal members of the committee, which also includes one representative from each State in the Union.

THE University of Ottawa was totally destroyed by fire on December 2. More than five hundred students from all parts of Canada, the United States, and Mexico were in residence. Fortunately they escaped, but several professors were injured, none, however, fatally. Everything in the building was destroyed, the total loss being estimated at 500,000 dollars.

THE first meeting of the court of the University of Liverpool was held on December 5, when Sir Edward Lawrence, Pro-Chancellor, presided. During the course of an address, proposing the adoption of the report and accounts, the chairman said the university had started its career with a property in land, buildings, and investments having a value of more than 500,000*l*. The subscriptions to the university movement in Liverpool amount to 170,000*l*.

A CONFERENCE was held on December 4 between the consultative committee of the Board of Education and representatives of various professional bodies in order to discuss the desirability and feasibility of the introduction of a system of school leaving certificates for England. Similar conferences with representatives of universities and of the teaching profession have previously been held. Lord Londonderry attended the conference for a short time in order to say a few words on behalf of the Board of Education. Sir W. Hart Dyke subsequently took the chair.

MR. R. B. HALDANE, K.C., M.P., presented the prizes and certificates at the Borough Polytechnic, Southwark, on December 4. In the course of his address, Mr. Haldane said that with regard to the movement for the creation of a great school of technology in London, there had been a certain amount of mystery as to its relation to polytechnics and its position generally. The reason that nothing had yet been disclosed was because things were moving, but with such deliberation that it was inexpedient to present pictures of the end when they had not got much beyond the beginning. They were only in the early stages at the present time. Conferences were taking place with various

experts, and it was hoped that the combined effort of the trustees of the Rosebery scheme, the Government, the great city companies, and the London University would produce a school which would be worthy of London. There would be no overlapping, but they would try to fill up the gaps, and the polytechnics would be linked to this higher school.

A School Nature-Study Union has been established to utilise and make better known facilities which already exist to encourage the study of nature by pupils in primary and secondary schools, and to supplement by work in several new directions the efforts of existing associations. The prospectus of the Union states that it is proposed to promote addresses to children by supplying lantern slides and specimens to teachers desirous of giving lessons on natural objects, and by providing qualified lecturers where desired; to assist in the organisation of school rambles and journeys, in the establishment of school museums and in the arrangement of conferences and natural history field days. The inauguration of a junior department, of reading circles, of circulating libraries for teachers, is also contemplated, as well as the publication of an official organ. Sir George Kekewich, K.C.B., is the president, and the Rev. C. Hinscliff, Bobbing, Sittingbourne, is the hon. secretary of the Union.

At the annual meeting of the governors of Yorkshire College on Monday, reference was made to the charter for the new university. Donations amounting to 36,000*l.* have been promised, provided that the sum of 100,000*l.* is raised. It is essential that their annual income should be largely increased if the new university is to take the position to which its central position among the industries of Yorkshire entitles it. Lord Allerton, who presided, remarked that they had reached the stage when they might consider the charter assured. The only point raised against the title of "The Victoria University of Yorkshire" was that it might clash with that of the Victoria University of Manchester, but Lord Allerton thought the distinction was well marked. A resolution was passed authorising the council to make any alterations in the draft charter which might appear to them desirable, and to promote a Bill for the incorporation of Yorkshire College in the university when founded, and to take such steps as would tend to secure the foundation of a university for Yorkshire.

Sir W. Anson, M.P., Parliamentary Secretary to the Board of Education, distributed the prizes to the students at the Goldsmiths' Company's Technical Institute, New Cross, S.E., on December 2, and delivered an address on education, during which he urged the claims of a wide culture and of a broad curriculum. In the course of his remarks Sir William remarked it was no disparagement to language, to history, and to literature to say that they did not explain the wonders of the world around them. It was no disparagement to science to say that it did not reveal to us the great facts and the great thoughts of the men of the past. He believed that practical business men were beginning to find that a liberal education was a good foundation for subsequent scientific and technological study when that had to be applied to business. They were beginning to discover that a man who had had what he would call a liberal education in language, history and literature had thereby laid a good foundation for scientific study or technological study, and that he was more useful for practical purposes than the man who had devoted his whole life to the limited area of one subject of scientific or technological pursuit.

A conference of Welsh county councils' representatives on the question of establishing a school of forestry for Wales and Monmouthshire was held recently at Haverfordwest. Mr. E. Robinson, of Boncath, who inaugurated the movement, explained that their object was to plant waste and at present unproductive woodlands in Wales. A school could be established with 100 to 200 acres of land to start with, and the option of acquiring a further 500 or 800 acres, and the total capital outlay ought not to exceed 5000*l.* to 8000*l.*, which could be contributed by the councils according to their rateable values. He believed the Government would contribute about half the amount required, and he assumed that an annual grant of 100*l.* from each of the councils would be sufficient to cover all out-of-pocket expenses, and give a good return on capital. There were about a million acres of waste land in the Principality which could grow timber. The planting would cost not more than 6*l.* an acre. Spread over thirty years, that would require a yearly grant of 100,000*l.* from the Government, the money to be repaid in that period by half-yearly instalments, and by the end of that time they should have plantations worth from 30,000,000*l.* to 40,000,000*l.* In the whole country there were 21 million acres of waste land and quite 8 millions suitable for planting, which in fifty years would be worth fully 650,000,000*l.* sterling. A resolution was adopted that it was desirable to establish a school of forestry for the whole of South Wales and Monmouthshire.

Mention has already been made (p. 70) of the conference of teachers to be held on January 7–9 under the auspices of the Technical Education Board of the London County Council. The meetings will be held, as in previous years, at the South-western Polytechnic, Manresa Road, Chelsea, S.W. The arrangements for the first day have been made in conjunction with the Geographical Association, and those for the second day in conjunction with the Modern Language Association. The subjects to be discussed in connection with the teaching of geography were announced in our previous note on the meetings. At the sixth meeting, on Saturday, January 9, at 2 o'clock, Prof. J. Perry, F.R.S., will take the chair. Addresses will be delivered by Mr. W. Hibbert on "New Apparatus for the Teaching of Electricity and Magnetism," and by Mr. R. W. Bayliss on "Practical Work in the Teaching of Geometry." A large exhibit of maps, globes, slides and apparatus illustrative of practical methods of teaching geography has been collected by the Geographical Association. Short explanatory lectures will be given on the collection on Tuesday afternoon, January 5, and every subsequent afternoon during the week. There will also be an important art exhibition, including an interesting loan collection of fifteenth and sixteenth century herbals and finely illustrated botanical works, together with a number of plant drawings by John Ruskin and his pupils. No charge will be made for admission to the conference or exhibitions. Application for tickets of admission should be made to Dr. Kimmins, 116 St. Martin's Lane, W.C., or Mr. C. A. Buckmaster, 16 Heathfield Road, Mill Hill Park, W.

In an address at the Municipal Technical Institute, West Ham, on Thursday last, Sir William White remarked that both elementary and higher technical education are necessary for national progress. There is the technical education which belongs to those who are trained from the first with the idea of becoming directors, managers, heads of businesses. This may be called the higher technical training for those who are intended to be captains of industry. Both kinds of training are necessary. The time has passed when the idea prevailed that technical instruction for the artisan should be limited to the workshop or the factory. Skill in handicraft and knowledge of practice and precedent no longer suffice. Every man engaged in industrial work should have the opportunity, if he so desires, of acquiring a knowledge of principles as well as of processes. For the workers themselves such knowledge is advantageous. Work done intelligently must be better done. From well-instructed workers better results are obtained than from others not so well informed. It is reasonable, also, to anticipate that from trained men should come more valuable suggestions for improvements in methods and processes that may reduce the cost of production and advance manufacture. In the stress of industrial competition, ever increasing in severity, it is absolutely necessary to the maintenance of our national position in the markets of the world that no advantage which technical training can give should be unrealised. Elementary technical instruction adapted to the working classes is by common consent a necessity of any scheme of State-aided technical instruction, and it seemed to Sir William White that to devote attention solely to higher technical instruction and to lavish our resources upon it exclusively, or even chiefly, would be a fatal mistake in the national interest. For sixty years the Admiralty has had a system of technical training for dockyard apprentices at the Royal dockyards, and there is no system of elementary technical education in existence that, in his judgment, has been so thoroughly proved. It is no exaggeration to say

that this Admiralty system of training has produced the majority of the men who are now occupying the leading positions in the shipbuilding industry of this country; that it has given to the private shipbuilders its leaders, who have risen from the working classes; and that it has produced many men holding responsible positions in other parts of the world.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, November 18.—Dr. W. A. Tilden, F.R.S., president, in the chair.—The union of carbon monoxide and oxygen, and the drying of gases by cooling, by Mr. A. F. **Girvan**. A series of experiments with various cooling agents was made, to determine whether aqueous vapour could be so far removed from mixtures of these two gases by cooling that they could no longer be exploded electrically. It was found that after having been cooled to a temperature of $-35°$ the mixture exploded feebly, and that if it had been cooled to below $-50°$ explosion did not occur; whence it appears that there must be at least one molecule of water in 24,000 molecules of the mixture in order that such mixtures may explode.—Simplification of Zeisel's method of methoxyl and ethoxyl determinations, by Dr. W. H. **Perkin**, sen., F.R.S. The vertical condenser and washing bulbs are dispensed with, it having been found that the hydriodic acid is completely retained by using a long-necked distilling flask with its side arm arranged to slope slightly upwards.—The rusting of iron, part ii., by Dr. G. T. **Moody**. The salts which inhibit the formation of "rust" on iron are divisible into two classes, viz. those which are strongly alkaline, and therefore absorb carbon dioxide, *e.g.* sodium phosphate and borate, and those which are decomposed by carbon dioxide, *e.g.* sodium nitrite, acetate, and formate. The author is of opinion that the non-formation of "rust" in presence of these salts is due, therefore, to their removal of carbon dioxide from the air, and not, as was suggested by Dunstan, to their property of destroying hydrogen peroxide.—Constitution of ethyl cyanoacetate. Condensation of ethyl cyanoacetate with its sodium derivative, by Messrs. F. G. P. **Remfry** and J. F. **Thorpe**.—The action of water and dilute caustic soda solutions on crystalline and amorphous arsenic, by Mr. W. T. **Cooke**. Amorphous arsenic is dissolved to a minute extent only, by prolonged ebullition of the element in water or aqueous solutions of sodium hydroxide even in presence of air. The crystalline form of the element, on the other hand, is also only slightly soluble in water and caustic soda solutions in presence of inert gases, but in presence of air the solubility is greatly increased.—Note on a double chloride of molybdenum and potassium, by Prof. G. G. **Henderson**. A description of the method of formation and of the properties of this salt, the composition of which is represented by the formula $3KCl,MoCl_3,2H_2O$, was given.—The action of benzamidine on olefinic-β-diketones, by Dr. S. **Ruhemann**.—Dissociation constants of trimethylenecarboxylic acids, by Messrs. W. A. **Bone** and C. H. G. **Sprankling**. A comparison of the values of these dissociation constants with those of the corresponding saturated open-chain acids shows that the formation of a closed ring increases the values of these constants.—The elimination of hydrogen bromide from bromo-*gem*-dimethylsuccinic acid and from bromotrimethylsuccinic anhydride, by Messrs. W. A. **Bone** and H. **Henstock**.

Mineralogical Society, November 17.—Dr. Hugo Müller, F.R.S., president, in the chair.—Mr. R. H. **Solly** gave a detailed description of various minerals from the Binnenthal, five of which had not been identified with existing species. These five minerals all contain lead, arsenic and sulphur, but sufficient material for complete analyses has not yet been obtained. Three of them are red transparent minerals having each one perfect cleavage and a similar vermilion streak, but differing crystallographically: one is apparently orthorhombic with (100), (110) = 39° 16′, (010), (011) = 52° 57′ and (001), (101) = 42° 43′; another is oblique with $\beta = 78° 46'$, (100), (101) = 42° 22′ and (010), (111) = 37° 3′; while the third has a zone at right angles to the perfect cleavage with angles of approximately 30° and 60°. The other two minerals, which could not be identified with any of the other sulpharsenites of lead previously described by the author, are black with metallic lustre. One of these is oblique with $\beta = 81° 11'$, (100), (101) = 40° 7′, (010), (111) = 55° 26′; it has a perfect cleavage (100), and, like liveingite, exhibits no oblique striations on the planes in the zone [100, 001]. The other mineral is also oblique with $\beta = 89° 40'$, (100), (101) = 46° 18′, and (010), (111) = 59° 56′; it has a perfect cleavage (100), and, like rathite, exhibits numerous oblique striations on the planes in the zone [100, 001]. On fine brilliant crystals of sartorite recently obtained by the author he has been able to confirm the oblique symmetry which he had previously announced, and to determine accurately the elements, $\beta = 88° 31'$, (100) (101) = 54° 45′, (010) (111) = 69° 52½′. Amongst other specimens from the dolomite of the Lengenbach in the Binnenthal, the author exhibited and described peculiar rounded crystals of galena resembling seligmannite, hyalophane crystals twinned according to the Carlsbad law and showing three new forms, a green mica which was determined to be anorthic, albite and biotite, minerals which have not yet been hitherto recorded from the locality, and barytes in green crystals. Of specimens from the Ofenhorn, the author exhibited some remarkably fine crystals of anatase, and crystals of laumontite, a mineral new to the locality.—Mr. L. J. **Spencer** described crystals of adamite from Chili which were remarkable for their strong pleochroism.—Mr. G. F. Herbert **Smith** discussed the prismatic method of determining indices of refraction. From observations of the angles of incidence and deviation the refractive index and direction of the wave-front in the crystalline medium could be found. By using pairs of faces in the same zone and different angles of incidence a series of refractive indices is obtained which, when plotted with the direction angle as ordinate, gives in general a double curve. Three of the critical values are the principal indices, the fourth corresponding to the direction parallel to the zone-axis. The angles of polarisation with respect to the zone-axis provide a means of discriminating between the doubtful values. A description was given of an inverted goniometer whereby observations could be made in media other than air.

Linnean Society, November 19.—Prof. S. H. Vines, F.R.S., president, in the chair.—The Rev. John **Gerard**, S.J., exhibited a fasciated rose sent by the Rev. J. Dobson, of St. Ignatius's College, St. Julian, Malta, with this note:—"A freak of a white climbing rose, in which eight or nine blossoms with their stalks have grown together."—The Rev. R. Ashington **Bullen** brought for exhibition an albino mole, from a farm near Bagshot; it was wholly of a light fawn colour, and no similar specimen had been seen for at least twenty years, though many moles had been trapped on the same farm.—Dr. M. T. **Masters**, F.R.S., gave an abstract of his paper, a general view of the genus Pinus. The author stated that the object of the paper was to discuss the nature and value of the characters made use of in discriminating the various species of Pinus, and to supply additional points of distinction derived from the anatomical structure of the leaf and other sources. The author has framed an analytical table of the species, which, although mainly artificial, may be of assistance hereafter in facilitating the determination of the species, and in arranging them in more natural groups. The two main divisions adopted are the thin-scaled pines or Tenuisquamæ, and the thick-scaled pines or Crassisquamæ, according to the relative thickness of the cone-scales. Further subdivisions are founded on various points of distinction.—Contributions to the embryology of the Amentiferæ, part ii., *Carpinus Betulus*, by Dr. Margaret **Benson** and Miss Elizabeth **Sanday**. More than 500 accurately orientated, stained and mounted series of sections were obtained through ovules containing the earlier stages in the development of the numerous embryo-sacs, until the segmentation of the definitive nucleus and of the egg occurred. Former observations (see part i. in *Trans.* Linn. Soc., ser. 2, bot. iii. (1894), pp. 409–424) were confirmed and the following new facts obtained. The polar nuclei meet at the neck of the cæcum, descend together and ultimately fuse near its base. The pollen-tube enters the sac in their vicinity, and provides some means of exit for one male gamete, which seems to be emitted into the cæcum

and makes its way to the definitive nucleus. Meanwhile the other male gamete is carried up by the tube and emitted into the substance of the egg, with which it fuses after a short delay. A wall is now formed round the egg, and when a considerable amount of endosperm is present, segmentation of the egg commences.

Royal Microscopical Society, November 18.—Dr. Hy. Woodward, F.R.S., president, in the chair.—Dr. Ed. **Horder** exhibited and described a metal clinical case for blood film work, &c.—Mr. **Taverner** exhibited on the screen two photographs of the leg of a water-mite which he had taken through the separate tubes of a binocular microscope to demonstrate that the images were dissimilar and capable of producing a true stereoscopic effect; if they were alike, the apparent solidity of the object as seen through the binocular microscope would be only a mental effect. He also exhibited in a stereoscope enlarged prints of the pair of photographs, which clearly showed that a true stereoscopic effect was produced.—Prof. J. D. **Everett**, F.R.S., read a note on Lord Rayleigh's paper of 1896, one part of which he had found specially difficult, namely, that in which the transition is made from direct to oblique illumination of a grating under the microscope. He had recently found a more direct mode of deducing the results there established, and that was set forth in the present communication. Lord Rayleigh, to whom he had submitted the note, said that on a cursory examination the new method of deduction seemed to be correct. Prof. Everett then proceeded to explain his proof by diagrams and formulæ on the blackboard.—Mr. W. **Wesché** gave a *résumé* of his paper on the mouth parts of the Nemocera and their relation to the families in Diptera, illustrated by a number of drawings shown on the screen by the epidiascope, and mounted specimens exhibited under microscopes.

Cambridge.

Philosophical Society, November 23.—Dr. Hobson, vice-president, in the chair.—The horse in Iceland and the Færöes, by Mr. F. H. A. **Marshall** and Mr. Nelson **Annandale.**—Note on the proportion of the sexes in *Carcinus maenas*, by Mr. R. C. **Punnett.**—On the transmission of earthquake waves through the earth, by the Rev. O. **Fisher.**—The action of ultra-violet light on moist air, by Mr. J. H. **Vincent.**—Experiment to show that negative electricity is given off by a metal exposed to Röntgen rays, by Prof. **Thomson,** F.R.S. Dorn, as well as Curie and Sagnac, have in different ways shown that a metal exposed to Röntgen rays gives out kathode rays; this can be shown very simply by mounting a small gold-leaf electroscope on a quartz support in a vessel in which a very good vacuum can be produced; when the vessel is exhausted and the gold leaves exposed to Röntgen rays they diverge, and on testing they are found to have a charge of positive electricity. If before exposure to the rays the leaves are charged negatively, then when the rays are applied the leaves at first collapse and then diverge, while if the initial charge is positive the divergence of the leaves increases from the time of putting on the rays. In this way is obtained a very direct proof that the gold leaves when exposed to the rays acquire positive and lose negative electricity.

Manchester.

Literary and Philosophical Society, November 3.—Prof. W. Boyd Dawkins, president, in the chair.—A collection of wind-worn pebbles of quartz and quartzite from an old raised beach near Waverley, North Island, New Zealand, together with photographs, was exhibited by the president. They have been cut by the sand driven by the wind into the characteristic *Dreikanter*, and might easily be mistaken for the work of the hand of man. The direction of the prevalent winds is shown by the amount of work done on each side or facet, the texture of the wind-worn being quite different from that of the wave-worn surfaces. The collection and photographs were made by Lady Constance **Knox** in 1900, and they will be given to the Manchester Museum, Owens College.—Mr. H. E. **Schmitz** gave an account of his experiments on the specific heats of metals at low temperatures. The author gave a summary of his determinations of the specific heats of various metals:—(1) between the temperature of liquid air and the ordinary temperature; (2) between the ordinary temperature and the temperature of steam. For the former temperature range two methods were used. Of these the first was the method of mixtures. The second method is similar in principle to Joly's well-known method of steam condensation, but here the weight determined is that of a deposit of ice. The final results show a variation of specific heat considerable in all cases, but more marked for metals of low than for metals of high atomic weight. This is shown by the following ratios of specific heat for lower range to specific heat for higher range for various metals:—aluminium 0·79, nickel 0·77, cobalt 0·78, copper 0·85, zinc 0·90, silver 0·92, tin 0·90, thallium 0·92, lead 0·96.

Paris.

Academy of Sciences, November 30.—M. Albert Gaudry in the chair.—On the scapular and pelvic fins of fishes, by M. Armand **Sabatier.**—Observations made at the island of Réunion on the eclipse of the moon of October 6, by MM. Edmond **Bordage** and A. **Garsault**. The observations were much hindered by clouds, only two good photographs being obtained, one being at the moment of greatest shadow.—The last sun-spot minimum, and remarks on the subject of the law of zones, by M. J. **Guillaume.** It is suggested that the distribution of sun-spots in latitude has not followed the law of zones, due to Spörer.—The problem of Cauchy relating to a particular class of surfaces, by M. W. **de Tannenberg.**—On the effective representation of certain discontinuous functions, as limits of continuous functions, by M. Émile **Borel.**—On a class of functional equations, by M. S. **Lattès.**—Articulations with a flexible plate, by M. A. **Mesnager.**—On the temperature of flame, by M. Ch. **Féry.** After a critical examination of the errors involved in the use of thermocouples, an alternative method is proposed in which no solid body is introduced into the flame. The measurement is made by the production of the reversal of a metallic line, by means of rays emitted by a solid body carried to any convenient temperature. The method is accurate to about 10° C., and has been applied to the determination of the temperatures of a Bunsen flame, an acetylene flame, alcohol, hydrogen, and oxyhydrogen blowpipe flames.—On some phenomena presented by mercury arcs, by M. **de Valbreuze.** Some of the peculiarities observed in starting the arc appear to indicate the existence of a superficial membrane on the mercury which opposes the passage of the current, especially in the cold.—On the suppression of magnetic hysteresis by the action of an oscillating magnetic field, by M. Ch. **Maurain.** Some recent experiments by M. Marconi and M. Tissot on a new receiver for wireless telegraphy have directed attention to the action of a rapidly varying magnetic field upon magnetisation produced under ordinary conditions. This action is attributed by M. Marconi to the suppression of the time lag, by M. Tissot to a modification of ordinary hysteresis with respect to the field. The quantitative experiments of the author agree with the latter of these hypotheses.—On the law of regular distribution of total magnetic force of the earth in France on January 1, 1896, by M. E. **Mathias.**—The magnetic anomaly of the Paris basin, by M. Th. **Moureaux.**—On the fusibility of mixtures of the sulphides of bismuth and silver, and of the sulphides of bismuth and antimony, by M. H. **Pélabon.** The fusibility curve of mixtures of bismuth and silver sulphides is a polygonal line presenting two minima and a maximum, the latter corresponding to a definite compound of the formula $Ag_2S.4BiS$.—Stimulating or paralysing influences acting upon manganese considered as a ferment, by M. A. **Trillat.** A study of the precise conditions under which the maximum oxidising effect is obtained from small quantities of manganese salts, acting as metallic ferments.—The systematic alkylation of arsenic, by M. V. **Auger.** An extension of Meyer's reaction; sodium methylarsenate is reduced by sulphurous acid to methylarsine oxide, and this is treated with methyl alcohol, soda, and the alkyl iodide.—The separation of iodine in the state of alkaline salt from bromides and chlorides by its transformation into iodic acid, and on the preparation of pure iodine, by MM. H. **Baubigny** and P. **Rivals.** The solution is oxidised in alkaline solution with potassium permanganate, the iodine

being thus converted into iodate, and after the addition of copper sulphate the bromine is distilled off in a current of air. On acidifying with sulphuric acid the chlorine can then be distilled off. Test analyses are given.—The microscopic study of the prehistoric bronzes of the Charente, by M. G. **Chesneau.**—On the eggs of *Bombyx Mori*, by M. Jules **Gal.**—On the egg production, fecundity, and sexuality in carnivorous fowls, by M. Frédéric **Houssay.** On the infectious exophthalmia of certain fresh-water fishes, by M. J. **Audigé.**—Contribution to the cytological study of the Ascomycetes, by M. **Guilliermond.**—On the geological synthesis of the eastern Alps, by M. Pierre **Termier.**—On a remarkable case of spontaneous crystallisation of gypsum, by M. Stanislas **Meunier.**—Luminous sensation as a function of the time for coloured light: technique and results, by MM. André **Broca** and D. **Sulzer.**—On the prediction of the yield of the sources of the Vanne, by M. Edmond **Maillet.**

DIARY OF SOCIETIES.

THURSDAY, DECEMBER 10.

ROYAL SOCIETY, at 4.30.—On the Integrals of the Squares of Ellipsoidal Surface Harmonic Functions: Prof. G. H. Darwin, F.R.S.—Preliminary Note on the Resistance to Heat of *B. Anthracis*: A. Mallock, F.R.S., and Lieut.-Col. A. M. Davis.

MATHEMATICAL SOCIETY, at 5.30.—Proof of a Formula in Elliptic Functions: Mr. R. J. Dallas.—On Many-valued Newtonian Potentials: Prof. A. C. Dixon.—A Generalisation of Neumann's Expansion of an Arbitrary Function in a Series of Bessel's Functions. Rev. F. H. Jackson.—Modes of Convergence of Infinite Series of Functions of a Real Variable: Dr. E. W. Hobson.—On Normal and Antinormal Piling: Prof. J. D. Everett.—On the Distribution of the Points of Uniform Convergence of a Series of Functions: Mr. W. H. Young.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Presentation to representatives of the Borough of Colchester of a historical picture representing Dr. Gilbert in the act of showing his electrical experiments to Queen Elizabeth and her Court.—The Slow Registration of Rapid Phenomena by Strobographic Methods: the "Ondographe" and "Puissancegraphe" (Wave Recorder and Power Recorder): M. E. Hospitalier.—The Magnetic Dispersion in Induction Motors, and its Influence on the Design of these Machines: Dr. Hans Behn-Eschenburg.

SOCIETY OF ARTS, at 4.30.—India's Place in an Imperial Federation: J. M. Maclean.

FRIDAY, DECEMBER 11.

PHYSICAL SOCIETY, at 8.—A Method of Mechanically Reinforcing Sounds: Rev. T. C. Porter. The Simmance-Abady "Flicker" Photometer: Messrs. Simmance and Abady.—Exhibition of a Conductometer: R. Appleyard. A Model to illustrate various Properties of Wave-motion: Prof. L. R. Wilberforce.

ROYAL ASTRONOMICAL SOCIETY, at 5.—The Rotation Period of the Planet Saturn: W. F. Denning.—The Shower of Leonids in 1903: G. W. Hough.—*Probable Papers*:—Two Drawings of the Mare Serenitatis by John Russell, R.A., affording some hitherto Unpublished Evidence as to the appearance of Linné in the Year 1788: A. A. Rambaut.—On Graphical Methods of finding the Time of Sunset at any Place: H. H. Turner.—On Oscillating Satellites; Second Paper: H. C. Plummer.—An Examination of the Relative Star Density in different Parts of the Plates forming the Harvard Photographic Star Map: J. C. W. Herschel.

MALACOLOGICAL SOCIETY, at 8.—On *Pleuronautilus pulcher*, sp. nov.: G. C. Crick.—Description of a New Species of Cassis: E. A. Smith.—On the Mollusca procured during the *Porcupine* Expedition 1869–1870, Supplemental Notes, Part I.: E. R. Sykes.—Notes on the Nervous System of Pelecypoda: R. H. Burne.

MONDAY, DECEMBER 14.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—The Patagonian Andes: Col. Sir T. H. Holdich, K.C.M.G., K.C.I.E.

VICTORIA INSTITUTE, at 4.30.—The Genesis of Nature: Rev G. F. Whidborne.

SOCIETY OF ARTS, at 8.—The Mining of Non-Metallic Elements: Bennett H. Brough. (Cantor Lectures. IV.)

TUESDAY, DECEMBER 15.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Deposits in Pipes and other Channels conveying Potable Water: Prof. J. Campbell Brown.—The Purification of Water Highly Charged with Vegetable Matter; with Special Reference to the Effect of Aëration: Osbert Chadwick, C.M.G., and Bertram Blount.

SOCIETY OF ARTS, at 8.—The British Silk Industry: Frank Warner.

ROYAL STATISTICAL SOCIETY, at 5.—The Metrical System of Weights and Measures: Alex. Siemens.

WEDNESDAY, DECEMBER 16.

CHEMICAL SOCIETY, at 5.30.—On the Relative Strengths of the Fixed Bases and of Ammonia as Measured by their Action on Cotarnine: J. J. Dobbie, A. Lauder and C. K. Tinkler.—New Halogen Derivatives of Diphenyl and Dihydroxy-diphenyl: J. C. Cain.—(1) Constitution of Nitric Peroxide; (2) Sabatier's Nitroso-disulphonic Acid: E. Divers.—Notes on some Natural Colouring Matters: A. G. Perkin and E. Phipps.—The Estimation of Methyl Alcohol in Presence of Ethyl Alcohol: T. E. Thorpe and J. Holmes.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—Some Account of the Meteorological Work of the late James Glaisher, F.R.S.: William Marriott.—On certain Relationships between the Diurnal Curves of Barometric Pressure and Vapour Tension at Kimberley, South Africa: J. R. Sutton.

ROYAL MICROSCOSICAL SOCIETY, at 8.—On the Structure and Affinities of the Genus Porosphæra: Dr. George J. Hinde, F.R.S.—Exhibition Slides illustrating the Development of an Ascidian: F. W. Watson Baker.

GEOLOGICAL SOCIETY, at 8.—The Igneous Rocks Associated with the Carboniferous Limestone of the Bristol District: Prof. C. Lloyd Morgan, F.R.S., and Prof. S. H. Reynolds.—The Rhætic Beds of England: A. Rendle Short.

SOCIETY OF ARTS, at 8.—The Science of Taxation and Business: Sir William H. Preece, K.C.B., F.R.S.

THURSDAY, DECEMBER 17.

LINNEAN SOCIETY, at 8.—On the Dacoglossa; a Study in Evolution H. J. Fleure.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.

FRIDAY, DECEMBER 18.

INSTITUTION OF MECHANICAL ENGINEERS, at 8.—An Inquiry into the Working of various Water-Softeners: C. E. Stromeyer and W. B. Baron.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Action of the Sea upon the Foreshore: C. B. Case.—The Causes of the Loss of Beaches: F. W Cable.

CONTENTS.

THURSDAY, DECEMBER 17, 1903.

GEIKIE'S GEOLOGY.

Text-book of Geology. By Sir Archibald Geikie, F.R.S. 4th Edition, revised and enlarged, 2 vols. Pp. xxi + 702; ix + 705 to 1472. (London: Macmillan and Co., Ltd., 1903.) Price 30*s*. net.

WHEN Sir Charles Lyell found that, owing to the rapid progress of geology, his early treatise must be extended beyond the limits of one handbook, he divided his subject into two parts. In the "Elements" he described the ancient changes of the earth and its inhabitants, as illustrated by geological monuments, and in the "Principles" he treated of the modern changes of the earth and its inhabitants considered as illustrative of geology. In the Elements we have a selection of facts upon which geologic history is founded; in the Principles we have a statement of the laws which have governed those changes based not only on the records of the past, but also and chiefly upon the observation of what is now going on in the present. Thus the Principles, which include that which we arrive at last, is, as its name implies, that which from an educational point of view we take first.

Sir Archibald Geikie has found that, in keeping his admirable text-book up to date, he has accumulated more material than could be conveniently contained in one volume, and has therefore issued it in two; but these are two volumes of one work, in fact the break takes place in the middle of one of his subdivisions of the subject—not inconveniently, however, as the first volume ends with the description of the aqueous deposits, and the second begins with the igneous rocks, both of which are included under structural geology. When, however, we look into the work, we see that its future is suggested not by its separation into two volumes, but by its subdivision into seven books.

The subject of the first book is the earth's place in the solar system, and the effect of the various cosmical forces acting upon it, in producing or modifying the geological condition of its crust. These have to be taken account of in discussing almost any geological question, whether glacial or volcanic phenomena, climatal conditions, the distribution of life, the age of the earth, or even such a question as the lateral erosion of river valleys, which, as some hold, depends largely upon the same influences as those which control the direction of the trade winds and ocean currents. The Garonne and the Volga, for instance, the one running north, the other running south, cling to their right bank, owing, it is suggested, to the rotation of the earth as they run at an ever increasing or decreasing distance from the axis of rotation. Although we must allow that this influence is a *vera causa*, always acting, and tending to deflect such running waters east or west, still, one cannot but feel that the variations in the level of the river beds, the winding of their courses, and the earth movements, which are known to have taken place in recent times over the areas in question, must have been far more important factors in regulating the course of the streams.

In the Second Book we learn about the materials of which the earth is composed, the chemical constituents of the crust, their mode of aggregation into what are known as minerals, and the methods of discrimination and classification of the sedimentary and igneous rocks; of rocks in the building up of which living organisms have played a part, and of rocks which have been altered by mechanical, chemical, or thermal agents so much that it is often difficult to recognise what their original character was. In this book we have glossaries of rock-forming minerals, of rocks of different composition and origin, and of various accessory substances, many of which are of economic value.

The author does not propose to treat specially of economic questions, but no one can understand the distribution and methods of obtaining coal, oil, metals, underground waters, and other products of the earth, without such a knowledge of their origin and mode of occurrence as may be gained from this work.

The Third Book deals with earthquakes and volcanoes, and has to do with the causes of upheaval and subsidence, the effects produced by internal heat, hydrothermal action, pressure and the accompanying chemical and mineralogical changes. These are subjects to which our author has paid special attention—"quorum pars magna fui," he might justly say of them—and for this reason as well as from their own intrinsic importance, we welcome his fuller treatment of them. In the second part of the same book he discusses denudation and its correlative deposition, and all the various forces of air, water, and ice, and of living things, by which they were brought about.

The changes which have taken place in the interior of the earth we should, at first sight, have thought to be one of the last subjects to which experimental research could have been applied; yet we learn that towards the end of the eighteenth century De Saussure set himself to study the possible derivation of rocks, by fusing samples of them, and judging whether, as had been alleged, some had arisen from the melting of others; but Sir James Hall more fully realised how far the processes of nature might be imitated by man, and about a hundred years ago described a series of ingenious experiments, by which he demonstrated the possibility of producing either a vitreous or a stony condition in fused rocks, according to the rate at which they are allowed to cool. Daubrée followed up this kind of experimental geology, and showed not only that various minerals usually found associated with volcanic and metamorphic rocks could be developed in the laboratory in their proper crystalline form, but also that enclosures and structures, analogous to those found in ancient schistose, and altered rocks could be artificially produced.

In Book IV. our author follows up his explanations of the *modus operandi* with an account of the results produced. He now describes the arrangement of the materials of the earth's crust, first of all considering the sedimentary rocks, their bedding and joints, their dip and strike, their cleavage and faults; also the pro-

trusion of solid masses and other phenomena connected with stratigraphical structure.

Here we have only just arrived at the end of the first volume of the present issue. The second volume begins in the middle of Book IV., with a continuation of the description of the manner in which the earth's crust has been built up and modified. This second part, however, refers to the action of internal heat and pressure, that is to say, it deals with rocks of igneous origin, whether superficial or deep-seated, and this leads to the consideration of earth movements, without which we should be unable to examine such rocks at all. Incidentally he here describes the mode of formation of veins and lodes.

Book V. gives a series of very much condensed, but still very useful notes on fossils and their place and use in geological investigations. This might be greatly extended.

Then follows in Book vi. the whole of systematic stratigraphy.

Our author arranges the stratified rocks under fifteen heads, and treats of their general characters, their flora and fauna, and their local development at home and abroad; but this, again, our author could easily develop into at least five volumes, representing the five groups under which the whole of historical geology could be very conveniently arranged.

In the seventh and last book he deals with the geographical features of the earth's surface, as affected by its geological character, and the arrangement of the materials of which it is composed.

There are buried in this text-book an immense number of facts vastly interesting to the general reader, and especially to the traveller who goes about with his eyes open, but without knowledge to follow the processes by which nature brings about the wonderful results observed. For instance, how seldom he realises when he sees the great blocks of travertine, so commonly used for building in Rome, that this *lapis Tiburtinus,* modified by Italian lips into travertino, is not a rock built up by the same kind of sediment as that of which most of the building stones he has seen elsewhere are composed, but that it is carbonate of lime which has been thrown down from chemical solution, and that plants have helped to collect it, while another similar rock, as commonly used elsewhere, has been collected by small animals, particle by particle, out of the sea water in which it was dissolved. Or if he is looking at those marvellous relics of volcanic activity, the geysers, which heap up silica instead of carbonate of lime, he will find that there also a small confervoid alga helps to collect the pasty material which afterwards hardens into flint. These are examples of scientific facts which would not force themselves upon the observation of the ordinary tourist, but which it would greatly add to his enjoyment of travel to know. Or, to take another more abstruse example, the study of the earth's satellite has suggested that the scars and pits upon it are due to the impact of aggregations of matter, and a similar bold hypothesis has been offered in explanation of certain depressions upon the earth. A basin-like hollow among the sandy mounds of Arizona was caused, it was suggested, by the impact of a meteoric body now possibly buried out of sight below, while the basin of the Atlantic, according to others, marks the area from which the material of the moon broke away from its moorings and commenced its long spiral spin round the earth. Such flights of imagination have often given us working hypotheses, which after pruning and shaping have found a place among the explanations of the order of the world. While we welcome all such tentative interpretations of phenomena, we must carefully weigh the evidence adduced, and not too hastily say proven or not proven.

The work is encyclopædic in character and arrangement, and, but that, alas! the question of cost has to be taken into consideration, we should gladly welcome its appearance in a dozen or more goodly volumes, the contents of which would be suggested by its present division into Books, some of which, as we have suggested, might be expanded into more than one volume. Then we might ask for larger type, instead of as now, 800 words to a page, and also for many more of the author's own clever sketches, and more illustrations such as those he has so judiciously selected from other sources.

NEW TEXT-BOOKS OF GEOMETRY.

Practical Plane and Solid Geometry. By I. H. Morris and J. Husband. Pp. viii+254. (London: Longmans, Green and Co., 1903.)

First Stage Practical Plane and Solid Geometry. By G. F. Burn. Pp. viii + 240. (London: W. B. Clive, University Tutorial Press, Ltd., 1903.) Price 2s.

Examples in Practical Geometry and Mensuration. By J. W. Marshall, M.A., and C. O. Tuckey, M.A. Pp. xii + 70. (London: George Bell and Sons, 1903.)

Elementary Geometry. Section ii. By Frank R. Barrell, M.A., B.Sc. Pp. viii+169 to 284. (London: Longmans, Green and Co., 1903.) Price 1s. 6*d*.

Theoretical Geometry for Beginners. Part ii. By C. H. Allcock. Pp. viii + 123. (London: Macmillan and Co., Ltd., 1903.) Price 1s. 6*d*.

Notes on Analytical Geometry. By A. Clement Jones. Pp. iv+172. (Oxford: Clarendon Press, 1903.) Price 6*s*. net.

Elementary Graphs. By W. M. Baker, M.A., and A. A. Bourne, M.A. Pp. iv+34. (London: George Bell and Sons, 1903.) Price 6*d*. net.

TEXT-BOOKS in this country which deal with the practical applications of geometry naturally follow the South Kensington division of the Board of Education, a department of the public service which has always taken a leading part in the spread of this branch of knowledge. The department has two distinct syllabuses, one for the guidance of art classes, the other for science. Both syllabuses have quite recently been revised and considerably extended, and are well abreast of the times. Although the two schemes have parts in common, there is an increasing tendency for them

to develop along divergent lines. Thus for art students one section of geometry to which great attention is paid is that relating to decorative geometrical designs, the study of which requires the drawing of many inscribed and circumscribed figures, patterns, &c. For science students this branch is of comparatively little interest. On the other hand, the geometry of vectors, a subject of first importance in science, has little attraction for the artist. Again, a student of science finds great use for his graphical constructions in the making of numerical computations, and the subject for him is becoming more quantitative in character. It is thus inadvisable to compile a text-book which shall endeavour to meet the wants of both classes of students; the first two books under review are written for science classes, and are adapted to the first stage of the revised South Kensington syllabus in Science Subject I.

The text-book by Messrs. Morris and Husband contains a large number of problems (more than 300) in plane and solid geometry, the solution of each being described in detail. The diagrams are clear and well printed, and are conveniently arranged to face the text. Each chapter closes with a useful collection of exercises. The syllabus is very completely covered as regards the matter, but the method of treatment cannot be said to correspond with its spirit. The student is told everything in minute detail. He is not sufficiently encouraged to think and invent for himself, and it is difficult to see how his interest can be maintained and his mental faculties properly developed. The method employed in problem 123 is obviously incorrect, and will no doubt be altered at the first opportunity.

In the volume by Mr. Burn, it is evident that the author's main interest centres in solid geometry, and he teaches this branch of the subject well, the student being instructed how to make simple models for himself, these being effectively used along with drawing in order to obtain a good grasp of this somewhat difficult subject. Too little attention seems to be given to plane geometry, and the student is not well grounded therein. The treatment of vectors is also meagre, and displays an inadequate conception of the scope and importance of this portion of the subject. Unfortunately some of the diagrams are needlessly small, and are trying to the eyesight.

The remaining five volumes are concerned principally with theoretical geometry. The book by Messrs. Marshall and Tuckey is a collection of nearly 550 examples arranged in groups. "The examples on practical geometry are intended primarily to lead up to geometrical reasoning, and only secondarily to give manual dexterity." Many of the examples are associated with a rider (distinguished by italic type), the truth of which will become evident as the figure is drawn, and which the reader is asked to establish by deductive reasoning. We notice with satisfaction that Euclid's method for the common tangents to two circles is discarded as unpractical. The examples in mensuration might with advantage have been a little more experimental. For instance, it would have been a satisfaction to a student to verify the numerical value of π; and an example might have been inserted asking for the area of a circle, to be obtained by the method of counting squares. The table of four figure logarithms which the authors give will prove very useful. We think that a simple table of functions of angles should also have been inserted and made use of in connection with some of the examples, especially those in mensuration. Teachers will find this large collection of examples very convenient, but its value would be enhanced by a further development on modern lines.

The second instalment of Mr. Barrell's "Elementary Geometry" comprises portions of Euclid ii., iii., iv. and vi., with some additional matter. In few of the recent text-books on the subject are the advantages of the reform in geometrical teaching more conspicuous than in this volume. While adhering to a strictly logical sequence, the author uses his new freedom to very good purpose, illustrating the propositions by experimental work, by well selected concrete examples, and by the employment of arithmetic, algebra and trigonometry. The introduction of the sine, cosine and tangent in the admirable chapter on ratio and proportion, and the subsequent judicious use of these functions, is a very good feature. The book deserves to be extensively used, and the appearance of section iii. of the work, which is in preparation, will be awaited with interest.

The first part of Mr. Allcock's geometry (corresponding with Euclid i.) was published in the early part of the year. The work is now continued, and the present part contains the equivalent of Euclid iii., 1–34, and iv., 1–9, with some additional propositions, such as the properties of the nine-point circle, and some practical applications and exercises. The title of the book correctly describes its contents and scope, comparatively little attention being given to quantitative and experimental graphical work. For those who do not wish to be tied to Euclid's sequence, and yet who desire to retain a strictly deductive system, the book will be found eminently suited. It is well written and beautifully printed; it contains a large number of easy deductive exercises distributed throughout its pages; and at the end of the volume there is a collection of practical exercises requiring numerical answers, which are given.

Mr. Clement Jones's text-book is intended for students who, having already taken an ordinary course in elementary analytical conics, wish to continue their studies and to obtain a good working knowledge of the methods of analytic research. In establishing the numerous properties of conics, the elementary theory of equations is applied in a systematic and thorough manner, in connection with which extended use is made of the single variable in the equations to the lines and curves. In a final chapter an account is given of cubic curves, the same powerful and illuminating method being employed. At the end of the volume the student will find a very useful collection of more than 200 examples, mostly taken from university examination papers, and the answers to these, with hints for solution, are appended.

The use of squared paper by schoolboys is becoming universal, and Messrs. Baker and Bourne have done

well to issue separately the chapter on graphs from their recent text-book of elementary geometry. The subject is well introduced, and the young readers are led on by easy stages and well selected examples. In connection with the plotting of sines, cosines and tangents, a short table of these functions, from which the pupils could take out their own values, would have been very instructive if it could have been provided. It seems a pity that no mention is anywhere made of the slope of a curve; comparatively few persons have yet recognised that the practice of graphing affords a valuable opportunity of helping to put into more tangible shape the idea of a *rate* which is certainly possessed in a greater or less degree even by the very young.

A CAMBRIDGE TEXT-BOOK OF PHYSICS.

Electricity and Magnetism. By R. T. Glazebrook, M.A., F.R.S. Pp. viii+440; diagrams. (Cambridge: University Press, 1903.) Price 7s. 6d.

THE present work represents a first-year course of Dr. Glazebrook's lectures in electricity and magnetism when at Cambridge. It forms one member of a series of which "Mechanics," "Heat," and "Light" have already appeared. The issue of these manuals was undertaken in response to a request that his lectures might be printed for the use, primarily, of the students attending the practical classes at Cambridge. Thus Dr. Glazebrook rather apologetically explains the publication of another book dealing with elementary electricity.

It is true that the number of elementary text-books is legion, and a man may well hesitate before adding to their number. Yet we think that there is still room, and that if a book of superlative value appears it will not fail to find a welcome.

In attempting to estimate whether the present volume is a noteworthy addition to elementary literature, let us in the first place say that it has undoubtedly many excellences. The method followed throughout is that with which we are already familiar in the other members of the series.

This method consists in mingling the theoretic and experimental sides of the subject, so that in no place is a student very far from the experimental point of view. Many of the experiments are intended apparently to be done only by the lecturer, but fifty-seven are specially described as instructions to a student. This double method involves considerable repetition, as the same statement which is made in the general text often appears again in the description of the experiment. No doubt, however, Dr. Glazebrook has found by experience that a junior student can hardly be told a thing too often, and repetition certainly does not err on the side of indefiniteness. Again, there is a considerable amount of repetition in the text itself. A general induction is made from some experiment, and this leads to a definition. The definition in many cases consists only of a repetition of the previous statements in a rather more formal shape. This, again, may be an advantage from the student's point of view, but it must be admitted that it tends to make the book rather slow. We cannot imagine anyone (except a reviewer) taking it up and reading until the small hours before putting it down. However, it is essentially a class book, and the student may acquire an enthusiasm for science from his teacher, who will amplify the somewhat categorically imparted information, hence the lack of more life is not so important.

The statements made are usually clear and logical. In some cases we are not sure of the logic. Thus, take the following sentence:—

"We have already seen that the electrification of a conductor may be the manner in which we recognise a state of stress set up in the dielectric round the conductor" (p. 40).

Should not the logic of this sentence be inverted? Is it not the stress in the medium which is directly investigated, and from which the state of electrification is inferred?

Again, in stating the law of electric force, it is asserted to follow

"as a result of the experiments, that when two similarly charged bodies are at a distance apart which is great compared with their dimensions, there is a repulsion between them which is proportional to the product of their charges," &c. (p. 44).

Is it not more logical to say that we measure the electric charges of bodies as being proportional to the mechanical forces which arise in consequence of them?

Again, the "joule" is *defined* in terms of electrical quantities. This reversal of the true logical order will mislead the student, who will fail to see that it is a purely mechanical quantity.

These may seem merely finicking criticisms, but those of us who come largely into contact with students know how difficult it is to eradicate illogical notions acquired during their early training.

In some cases the information given is not sufficient. Thus, while considerable use is made of lines of force, we are not told how they are drawn so as to represent the *intensity* of the field.

Again, the lines in the diagrams on pp. 36, 37, are drawn on a completely different system from those on pp 38, 39, and there is no hint given of this. Of course, to the ordinary student this does not matter—he is accustomed to consider physics an esoteric science; but how confusing to the real student who tries to make out what the diagrams mean.

Again, *tubes* of force suddenly appear (without introduction) on p. 186 instead of lines.

On p. 377 it is stated that

"the total E.M.F. round the secondary is proportional to the total change in the number of lines of induction linked with it."

The whole chapter on electromagnetic induction, indeed, deals only with the total E.M.F. It is nowhere defined—the student will think it identical with electromotive force.

The figures are very good and instructive. Fig. 77, which shows the screening action of an iron ring, would be improved if the *refraction* of the lines at the surface of the iron were correctly represented. Again, the lines do not crowd between the cake and cover

of an electrophorus (Fig. 39) until the cover has been earthed.

In the further editions which will certainly be called for we should like to see a proof of the equation $R=4\pi\sigma$, although Dr. Glazebrook (p. 63) considers the proof to be beyond the limits of the book. It is so easily done for a sphere, and the case of a plane is obtained at once by expanding the sphere of infinity. It will also be an advantage if graphical representations of the forces of charges and currents are given.

The concluding chapters deal with technical applications (there is no mention of electric lighting), with electric waves, and with the electronic theory of discharge.

The volume is very well printed, and is remarkably free from printer's errors. But in one particular we must speak with great emphasis—the punctuation requires most thorough revision. Many sentences are unintelligible on first reading, although the wording is quite correct. We give the shortest illustration of this fault. The time "will also depend on the restoring couple being less when this is big, than when it is small."

PROF. JOHANNSEN ON HEREDITY.

Ueber Erblichkeit in Populationen und in reinen Linien. Ein Beitrag zur Beleuchtung schwebender Selektionsfragen. By W. Johannsen. Pp. 68. (Jena: G. Fischer, 1903.)

PROF. JOHANNSEN has set himself a hard task, namely, the reconciliation of the views of Prof. de Vries on mutations with those of the biometric school, particularly with the Galtonian theory of regression. We say a hard task, because to perform the task of reconciliation requires, on the one hand, an intimate knowledge of the mathematical theory of statistics, and on the other a power of clearly defining the exact biological points which are at issue. It is not an easy matter to distinguish between a so-called mutation and an extremely improbable variation; indeed, the utmost caution is needed when we remember that in every case of continuous variation it has been shown theoretically that the extreme variations in populations of even many thousands must be separated by wide intervals, the wider the more extreme the variations.[1] Clearly it is practically impossible to distinguish straight off between a "mutation" and an extreme variation in the biometric sense. Both parties would probably agree that only observation of the results of propagating from the individual thus classified could serve as a criterion between the two views.

According to the biometricians, the type of the variation would regress in the offspring, either to the population mean if a "pure line" did not exist, or to the "type of the pure line" if such did exist; in the latter case a change in type from that of the "pure line" could then be produced by selective breeding within the line for a generation or two. According to de Vries, no further change could take place until a new "mutation" appears. Unfortunately, de Vries's own experiments are very far from conclusive in this respect. Thus in his experiments on clover he was not content with the discovery of a mutation, but went on stringently *selecting* year after year, in exactly the manner in which the biometrician would suggest that a "stock" should be formed from extreme variations. According to the biometrician, two or three generations of selection will form a stock which, while very variable about its type, will yet breed true, or with but small regression.

Prof. Johannsen seems to assume that this result of biometric theory (1898) is the view only of de Vries, who published his conception of the line "as perfectly constant and yet highly variable" three years later. Thus the criterion between the "Biometriker," as Johannsen calls them, and the "Mutators," as we may perhaps call their opponents, cannot be made to turn on the breeding true of "pure lines" or on the variability of such lines about their type. It can only turn on whether, within the "pure line," there exists regression and progression when we breed from variants which are not so extreme as to be at once classed by the "Mutators" as new mutations. Prof. Johannsen had a good opportunity for dealing with this problem in his experimental observations on the bean *Phaseolus vulgaris*, but he has unfortunately not provided the exact data on which it could be answered. He has shown that the population of bean *seeds*, as distinguished from bean *plants*, exhibits Galtonian regression; he may, more doubtfully, be held to have shown that "pure lines" breed true. But this is no reconciliation of the biometric and mutational theories, for both parties accept the breeding true of pure lines.

Unfortunately Prof. Johannsen seems to think that a single bean seed may be taken as typical of a plant, and thus the whole inner meaning of allowance for homotyposis escapes him. If his view—that pure lines show no internal regression—were correct, then the correlation between mother and daughter plants ought to be perfect, for either of them represents the "pure line," and that is "völlig konstant." Unfortunately Prof. Johannsen has not determined this correlation, but from his published material it can be indirectly worked out for the case of the mean weight of the beans produced by nineteen mother plants and their daughter plants. The correlation thus obtained is 0.59 ± 0.13; this might be equal to the imperfect correlation of the biometricians, who find the value for man, horse and dog to be 0.5, but it is very far from the perfect correlation needed by those who assert that there is no regression within the pure line to its own type. Prof. Johannsen's own investigation of this problem (pp. 36–37) is quite fallacious; and this is owing, we think, to inexperience in the use of statistical methods. From this standpoint we should like to protest against any such crude process of determining goodness of fit as that of placing a normal curve down on seven or eight blocks forming a "histogram," and judging the look of the fit. No such test is valid, and, further, he has not yet shown that the normal curve of errors itself is suited to describe the phenomena referred to.

We hope Prof. Johannsen will continue his experi-

[1] Francis Galton's Difference Problem (*Biometrika*, vol. i. p. 390).

ments, but at the same time in this, as in so many other cases, we hold that statistical methods cannot be safely used without proper training. Experiments of a most laborious character may be rendered nugatory because the observer has not started with a clear conception of what statistical processes he is going to employ to deduce his results, nor what observations are needful if any conclusions at all are to be reached by legitimate numerical arguments. The book shows the increasing interest in the problems of inheritance and in biometric methods; it is characterised throughout by a courtesy of tone which is very pleasing when contrasted with some recent controversial papers on heredity; but it fails, and fails badly, to prove any definite point, because the author has not clearly stated his problem, and had he done so has really not the knowledge needful to deal effectively with statistical data.

OUR BOOK SHELF.

Die europäischen Laubmoose. By George Roth. Lieferung i. Band i. Pp. 128. (Leipzig: Wilhelm Engelmann, 1903.)

THE second enlarged edition of Schimper's "Synopsis muscorum Europæorum" was published in 1876, and a list of European mosses was given by the same bryologist in "Revue bryologique" seven years later. Since that time, in this country there have appeared Hobkirk's synopsis, Braithwaite's "Moss-flora," and Dixon's handbook. In other countries there has been the same advance in bryological records, to mention only Limpricht's compilation for Germany, Austria, and Switzerland, and Husnot's "Muscologia gallica," so that the time is ripe for a new European synopsis. The work undertaken by Dr. Roth is, on the one hand, rendered easier by the existence of these authentic catalogues, but meantime the number of recorded species has increased, so that whereas Schimper enumerates 900, the author estimates European species, exclusive of Sphagna, at 1300; of these about 600 occur in Britain

The greater portion of this, the first part, is given up to a general introduction, and only the last few pages are concerned with the enumeration of genera and species. The introduction is well written, and the author has throughout emphasised the various characters which are of immediate importance for identification and classification. There is an original chapter on the part which mosses play in the economy of nature, and some account of their distribution. The system of classification adopted by the author is nearly identical with that of Schimper and Limpricht, the critical features being the separation of Archidium as a special order, and the division of the Bryineæ into cleistocarpous and stegocarpous groups; British bryologists favour Lindberg's arrangement, in which the cleistocarpous mosses are split up amongst the other natural orders.

In the essential systematic part of the book there are only a few descriptions from which to form an opinion. The author leads off with the Andreæaceæ, as the Sphagnaceæ will not be included, and he makes fifteen species for Andreæa; of these several are only accorded the rank of varieties by other authorities, *e.g.* of the fifteen, nine have been found in Britain, and yet Dixon only allows at the most five species. The various countries from which the species have been recorded should, we think, be definitely stated. Another very desirable, indeed necessary, addition is the provision of tables to determine genera, and a separate species-key to each genus. The book is liberally illustrated, but the plates are far from pleasing, and the areolation of the leaves is very doubtfully shown owing to the small scale adopted for the drawings. There are obvious advantages in using a general synopsis rather than, or in addition to, the flora of a single country, so that the book is a very desirable one, but it would be made more useful by the insertion of analytical keys and critical notes dealing with the more doubtful species. The book is to be issued in eight parts at a cost of about three pounds.

Mechanics, Molecular Physics and Heat. By Robert Andrews Millikan, Ph.D. Pp. 242; diagrams. (Boston and London: Ginn and Co., 1903.) Price 7s.

THIS book represents the first portion of a college course in general physics, in which the primary object has been to establish an immediate and vital connection between theory and experiment. It has, therefore, been made neither a laboratory manual, in the ordinary sense of the term, nor yet a simple classroom text. Each section is introduced by a theoretic statement, and is followed by instructions with regard to an experiment to be performed. As it is only a twelve weeks' course which is represented, the experiments have had to be selected out of the large number of possible ones, and in making this selection the author has aimed at having one, and only one, experiment in illustration of each principle.

For example, there is but one general principle involved in the method of mixtures, whether it be applied to the determination of the specific heat of a solid or of a liquid, the latent heat of fusion or of vaporisation; hence only one laboratory exercise is provided in illustration of the method. This extreme pruning may sometimes be necessary in an introductory course, and where circumstances render it necessary the plan of the author is no doubt excellent. But we feel sure that such an abridgment is not to be desired. A student learns so much in finding out the variations in a method which are necessary to apply it effectively to different purposes that every opportunity for the discovery ought to be afforded.

The description of the selected experiments is excellently, if somewhat briefly, made. About half the book is devoted to mechanics, which in England is usually taken in a separate course. Each chapter is concluded with a few problems having considerable merit.

We have only to suggest that in the discussion of rotation it should be clearly brought out that the moment of the forces *must* be taken either with regard to the centre of mass or to an axis fixed in space, and further that the moment of inertia is not necessarily the same in the two cases.

Ostwald's Klassiker der exakten Wissenschaften. (Leipzig: Wilhelm Engelmann; London: Williams and Norgate, 1903.)

SEVERAL additions to Prof. Ostwald's important series of reprints of classical papers lie before us. We have space to do little more than mention the titles of the individual volumes, but, in general, we cannot forbear expressing pleasure at the increased facilities they afford for a student to become familiar with original papers connected with the exact sciences. Of course, to the English student, translations into English would be more acceptable. But, given a sufficient knowledge of German, the handiness of these volumes and the valuable annotations of the respective editors are sure to prove a great attraction.

The following are brief particulars:—

No. 135.—"Theorie der Gestalt von Flussigkeiten

im Zustand des Gleichgewichts." Gauss. Translated by R. H. Weber. Edited by H. Weber. (Pp. 73, price 1.20 marks.)

No. 138.—"Über die Bewegung der Körper durch den Stoss. Uber die Centrifugalkraft." C. Huygens. Edited by F. Hausdorff. (Pp. 79, price 1.40 marks.)

No. 20.—"Abhandlung über das Licht." C. Huygens. Second Edition. Revised by A. von Oettingen. This is a translation of the famous essay in which the wave theory of light was developed and the peculiar refraction of Iceland spar was investigated. (Pp. 115, price 2.00 marks.)

No. 134.—"Experimental-Untersuchungen über Electricität." Faraday. Edited by von Oettingen. Sixteenth and seventeenth series, in which the source of the E.M.F. of a voltaic cell is investigated. (Pp. 103, price 1.60 marks.)

No. 136.—Ditto. Eighteenth and nineteenth series, describing his investigations on the development of electricity by the friction of water and vapour in other bodies, and on the relations of magnetism and light. (Pp. 58, price 1.20 marks.)

No. 21.—"Über die Wanderungen der Ionen während der Elektrolyse." Hittorf. First Part. Edited by Ostwald. Second Edition. (Pp. 115, price 1.60 marks.)

No. 137.—"Abhandlungen zur Thermodynamik chemischer Vorgänge" (1869–1881). Horstmann. Edited by van 't Hoff. (Pp. 72, price 1.20 marks.)

No. 139.—"Thermodynamische Abhandlungen über Moleculartheorie und chemische Gleichgewichte" (1867–1872). C. M. Guldberg. Translated and edited by R. Abegg. (Pp. 85, price 1.50 marks.)

The last three numbers represent treatises which are familiar by quotation to all students of physical chemistry, and ought to be welcomed in this new form.

Principii di Stereodinamica. By Gian Antonio Maggi, Professor at Pisa. Pp. 264. (Milan: Ulrico Hoepli, 1903.)

STARTING with the formulæ connecting the coordinates of a particle of a rigid body referred to axes fixed in space with its coordinates referred to axes fixed in the body, the equations of motion of a rigid body moving in three dimensions are deduced from D'Alembert's theorem. The applications include the problems of motion under no forces, in which the equations are integrated by elliptic functions, the simple and compound pendulum, motion of a billiard ball, &c., and Lagrange's equations are also treated in this part. The second part deals with Hamilton's principle in its various forms, and the third with Jacobi's theorem. The work differs in many respects from the conventional English text-books, in which special attention is given to the properties of moments of inertia and numerical examples rather than to rigorous deductions of the fundamental equations. Those whose lot it is to lecture on "three dimensional rigid" will find a study of this book very useful and suggestive. G. H. B.

The Fields of France. Little Essays in Descriptive Sociology. By Madame Mary Duclaux (A. Mary F. Robinson). Pp. vii + 318. (London: Chapman and Hall, Ltd., 1903.) Price 5s. net.

THIS little book reveals the writer's love for rural France, and her anxiety "to set down chiefly the things I have seen for myself, or which have come under my own knowledge" (p. 13), is reflected in the reality of the descriptions and in their sustained interest. Though there is little of an exciting character in the pages, readers who value word pictures of the habits and customs of country folk will find pleasure in this book.

LETTERS TO THE EDITOR.

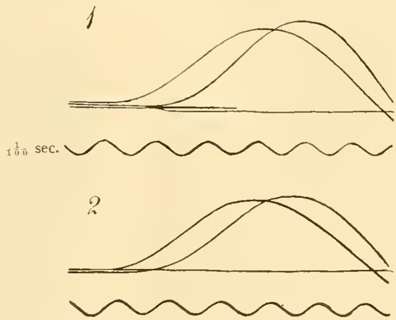
[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Velocity of a Nervous Impulse.

SIR W. GOWERS's dilemma (p. 105) is of the library rather than of the laboratory, and I should hardly care to appeal to differing book-data by different observers in evidence of an acceleration of nervous processes during the last fifteen years, either in the same or in different individuals.

I happen to possess records taken on myself in 1882 and in 1903, as well as upon my son, *aet.* fifteen, in May, 1903. In all three cases the velocity comes out at about 50 metres per second, as I read the records, but can easily be taken as indicating 60 metres if the rise of each curve from the base line is spotted a little differently. It is, in fact, advisable to examine the original data very closely before quoting velocities deduced from them, since very small differences in measurement along the abscissa multiply out to large differences of velocity expressed in metres per second.

Thus in the instances enclosed, taken from my son last May in an interregnum from Greek roots, the times, as I read them, are 0·0063 and 0·0053 sec., and the velocities 51·5 and 61·75 metres per second.



May 3, 1903.—W. W. Waller, *aet.* 15; nerve-transmission velocity; excitation above clavicle and at bend of elbow; distance = 0·325 metre. Time diff. 1, 0·0063 sec.: 2, 0·0053 sec. Velocity 1, 53 metres per sec. 2, 62 metres per sec.

The more carefully the records are taken and read the less inaccurately do the velocities come out. I think that Dr. Alcock's estimate of 66 metres per second is a somewhat closer approximation to the truth than my estimate of 50 metres, and *a fortiori* than the still lower estimate of 33·9 metres, which is that originally made by Helmholtz and Baxt in 1867. A. D. WALLER.

A Useful Empirical Formula.

THE very neat construction given by Prof. Perry in NATURE, December 3, p. 102, leads at once to the equation

$$\frac{\Delta y}{y-a} = \frac{\tan\beta}{\tan\alpha}\frac{\Delta x}{x};$$

and the assumed equation $y-a=bx^n$ gives $\dfrac{dy}{y-a}=n\dfrac{dx}{x}$

Hence, approximately, $n=\dfrac{\tan\beta}{\tan\alpha}$.

Why does Prof. Perry prefer to write

$$n=\frac{\log(1+\tan\beta)}{\log(1+\tan\alpha)},$$

which is less simple for computation?

11 Leopold Road, Ealing. J. D. EVERETT.

THE MASKED TAWAREKS.[1]

THE Tawareks, in common with other African tribes which live in the northern half of Africa, have long been an object of curiosity and interest to European scholars and travellers, but in spite of all the researches which have been made into the history of their origin and language, many problems concerning them remain unsolved to the present time. One thing about them is certain, which is that they have made their name to become a real terror among the peoples who live on the borders of their country, and although they inhabit a region which is estimated by Mr. Harding King to be as large as Russia, and are, indeed, a nation which will have to be reckoned with one day by civilised nations, no systematic attempt has been made to collect facts about and statistics of their country and its resources.

There are many theories about the origin of the Tawareks, but it is not easy to pin one's faith to any of them absolutely. They belong undoubtedly to the Berber race, and live in the wild places of the Sahara, *i.e.* the great "rocky" region which lies to the south of Algeria; they never come near civilised peoples if they can help it, and they only approach caravans belonging to other tribes in order to plunder them and to kill their owners. The track of their raids may be easily followed throughout the Sahara by means of the groups of graves and sepulchral monuments which they have scattered over the whole face of that dreary region of rock, sand, and sun, and the frequency with which such monuments are found suggests only too clearly the multitude of bloody raids which have to be laid at their door. They have one custom which distinguishes them from their neighbours, *i.e.* the men keep their faces covered by a mask, and they hide their features by these means even from the members of their own family circle.

To interview members of the Tawarek tribe and to take photographs of their faces were the chief objects which Mr. Harding King had in view when he made his journey of about six hundred miles into their country, and the volume before us, which gives a full account of his travels, is extremely interesting reading. We need not here refer to the earlier part of the book, which describes the preparations he made for his journey, for they are familiar to everyone who has tramped the desert in any part of the East, especially in northern Africa and the Sûdân, and we therefore pass on to the latter half of the narrative. The principal places which Mr. Harding King passed on his way were Saada, Bir Jeffir, Shegga, Mraier, Sidi Amran, Tougourt, Hassi, Mamar, and his travels in a southerly direction ended at Wargla; on his way back he struck off to the east at Tougourt, and, having visited Gomar El-Wad and Edemeetha, he turned to the north-west and directed his steps to Shegga, where he joined the road on which he had set out from Biskra.

[1] "A Search for the Masked Tawareks." By W. J. Harding King. Pp. viii+334; with forty-one illustrations and a map. (London: Smith, Elder and Co., 1903.) Price 12s. 6d.

Tougourt, though a most interesting place to see and examine for a short time, is not a healthy one to live in, and no one will blame a traveller for leaving it as soon as possible; it is an important market town, and possesses a mosque, of the interior of which Mr. Harding King gives an excellent view. Wargla, which marks the limit of our traveller's journey, was, and still is, a town of importance, but since the slave trade has been suppressed, and the large trading caravans from the south now dispose of their wares in Morocco and Tripoli, it has lost much of its wealth and position. The streets of Wargla are open to the sky, and the houses are well built and usually fairly well kept. There is a French fort here, in one of the walls of which is a monument to the brave men who fell in the luckless expedition of Colonel Flatters into the Sahara. The Tawareks were, of course, at the bottom of the mischief, but they were no doubt helped by the Senussi, who will, if we mistake not, give trouble in northern Africa when they find the fitting opportunity. The founder of the Senussi, Sayyid Muḥammad bin 'Ali es-Senussi, was born about 1808 at Mostaganem and died in 1859, and at the present moment his followers form one of the most powerful religious and political confederacies in northern Africa; had they joined the late Mahdi at Khartûm and supported his rebellion with troops, the result of the British expedition would have been very different.

FIG. 1.—Wargla. (From "A Search for the Masked Tawareks.")

On his return journey Mr. Harding King heard with delight that about half a dozen tents of the Tawareks were pitched near Edemeetha, for if he could but manage to get their owners to receive him

and to unveil their faces, the object of his travels would be attained. As soon as possible he set out for the Tawarek tents, and he was fortunate enough not only to be received, but to be invited to take snuff with them. He found that "they were all filthily dirty," for no true Tawarek ever washes. Such ablutions as are necessary for religious purposes are performed with sand or stone; occasionally, with the view of improving his appearance, he rubs himself with indigo. Mr. Harding King found that his hosts all had "thick, purring voices," a shifty manner, and large, lustrous, furtive eyes. By and by some of them lifted their "lithams," and so exposed the upper part of their faces, and he saw that some were white skinned, some very dark, and "their aquiline noses showed that no trace of a negro stain was present in their blood."

FIG. 2—A Tawarek Noble. (From "A Search for the Masked Tawareks.")

After a little time he was allowed to wander round their camp, and eventually succeeded in obtaining two photographs of a group of his hosts. A day or two later Mr. Harding King paid a second visit to the Tawareks, and good fortune enabled him to photograph a number of women in their tents; he found their hands small and neat, with long tapering fingers, their arms "the prettiest imaginable," their wrists "beautifully rounded," &c.; finally, the young Tawarek who was outside the tent removed his veil, and our traveller was rewarded by being allowed to take the photograph of which an excellent reproduction faces p. 315.

In a short appendix Mr. Harding King repeats a number of usually accepted statements about the Tawarek alphabet, but, naturally, contributes few new or startling facts. The Tawareks call their alphabet "Tifinagh," and they derived it from the Berbers; it may be descended from the old Libyan, but it is unlikely to be of any very great antiquity, and if it has any very close affinity with the Libyan characters on the Tugga Stone, which was set up by Atabân, the son of Yaphmatath, and which is now in the British Museum, it is not very much older, probably, than B.C. 400. Mr Harding King's narrative is very readable and modest, and is well illustrated by many good reproductions of photographs; it cannot be regarded as a scientific exposition of Tawarek lore, but it contains a great deal of knowledge collected at first hand by one who has no "axe to grind," and is therefore of value.

SIERRA LEONE.[1]

THE major portion of this work is devoted to a description of the native rising in the Sierra Leone Protectorate in 1898. Many examples are given of the hideous tortures with which the natives murdered those natives and European women and children who fell into their hands. But only those who have heard from actual word of mouth of those who had been through the insurrection can fully realise the hellish cruelty of the native. These chapters should be read by those who forget or do not know of what diabolical acts the native is capable. They should be remembered by those who nowadays urge us to "take the native with us" in our reforms. Justice to the native the Englishman will always measure out, but it will be long before the native can be treated as our social, intellectual, or moral equal. While we must not forget these terrible traits in the native character, we may yet do full justice to his many admirable points, and Captain Wallis's tribute to the men of the native frontier force who remained loyal throughout the rising is nobly deserved. It is well, too, that a book of this kind should have been written, recording, as it does, individual acts of bravery and heroic defences under the terrible conditions of the West African climate.

The portion of the book that will perhaps most interest the general reader will be the account of the secret societies, "the Alligator," "the Leopard," and others still, as Captain Wallis admits, existing, but yet much curtailed in their devilish operations. So much is here recorded of them that it would appear certain that the whole origin, meaning, and ramifications of these societies could be unravelled by a careful investigator with time and money at his disposal. "Sāss stick," the *mwavi* of British Central Africa, is still used in the protectorate, and we well remember the long journey made by us into the bush in search of the tree, which we found almost completely denuded of bark, showing that it was much in use. As the author points out, the subject of native medicine is still neglected, and although there are botanical gardens at Freetown and Songo, Aburi (Gold Coast) and at Lagos, we should be surprised to learn that any contribution to this subject ever came out of them.

[1] "The Advance of Our West African Empire." By C. Braithwaite Wallis. Pp. xv+318. (London: Fisher Unwin, 1903.) Price 21s.

In a chapter devoted to "our commercial policy," the native arts are considered, such as pottery and the weaving of cloths. The production of these should, in our opinion, receive all encouragement and careful direction before the trading companies have "improved" them out of existence with their cheap Manchester substitutes. Very wise, too, is Captain Wallis's advice that native customs and traditions should be cherished, except in so far as they manifestly clash with the higher ideals of Christian morality. The question of health can hardly be avoided in a book on West Africa, and the author is to be congratulated on having grasped the main facts of the mosquito malarial cycle. He is aware of the danger of camping in a native village—the almost invariable practice—for, broadly speaking, it is here only that the malarial mosquito is dangerous, because it has been infected with parasites by the native children, who form, so to speak, the great central depôts of malarial parasites in Africa. In a word, the first law of health in West Africa is efficient protection from this constant source of malarial fever, and a bungalow well isolated from native huts would mean many a European life saved. Our illustration of Government House, Bandajuma, on the contrary, shows things as they should not be. Those "deadly" huts (seen in the right-hand corner) mean constant danger to the European commissioner.

FIG. 1.—Government House, Bandajuma. (From "The Advance of Our West African Empire.")

The book is fully illustrated, but we think many of the illustrations might have been chosen with greater care. They give but little idea of the characteristic scenery of the country. Thus we sought in vain for the magnificent cotton trees or the beautiful unmatched "lines" of the mangrove tree. We think, too, the title is too comprehensive for the nature of the book. But the author deserves our thanks for having given us a straightforward account of the rebellion and some very interesting chapters on native customs. We have read the book with much pleasure, and in our own case with an added pleasure from familiarity with many of the scenes and faces represented in the illustrations. J. W. W. S.

THE IONISATION OF ATMOSPHERIC AIR.

MESSRS. ELSTER AND GEITEL have published an important paper in the *Physikalische Zeitschrift* (No. 9, pp. 522–530), "Ueber die radioaktive Emanation in der atmosphärischen Luft." They find that the abnormal conducting power of the stagnant air of cellars and caves, and the amount of induced radio-activity which can be obtained from such air upon a negatively charged rod suspended in it vary greatly in different regions. In some places such air is no more active than ordinary atmospheric air. Air sucked through a pipe of which one end is buried in the ground is generally active, like the air of most cellars and caves; tests of the activity of samples of such ground-air from different localities showed great variations, some being no more active than ordinary air. The activity of ground-air falls off at a rate comparable with the rate of decay of the radium emanation. If a portion of the soil of a region in which the ground-air is radio-active is isolated, it gives to a volume of air in contact with it abnormal conductivity which reaches its maximum in a few days. The soil retains this power for many months at least. The phenomena are all most readily explained by supposing that substances, which have the power of producing a radio-active emanation like that of radium, are distributed in varying amount among the materials composing the soils of different regions. In the latter part of the paper is an account of some interesting observations on the dependence of the radio-activity of atmospheric air upon meteorological conditions. The increase of the activity of the air which generally accompanies a fall of the barometer is attributed to the escape of ground-air into the atmosphere.

Herr Himstedt repeated and confirmed some of Messrs. Elster and Geitel's experiments upon ground-air (*Berichte* der naturforschenden Gesellschaft zu Freiburg, vol. xiii. p. 101). In the course of this work he found that air passed through a water air-pump acquires considerable conducting power, which persists (even when the air is dried and filtered after passing through the pump) for some days. He appears to have been unaware of the previous discovery of this phenomenon by Prof. J. J. Thomson. Himstedt gets identical results from distilled water, rain-water, and tap-water, whereas Thomson found distilled water and rain-water comparatively ineffective, the action being strongest with certain waters from deep wells, and being attributed by him to a radio-active substance contained in such water. Himstedt found, as Prof. Thomson had previously shown, that the activity of the air is not removed by an electric field; he proved, however, that it can be removed by passing through a tube cooled by liquid air. He believes that water brought into intimate contact with a gas exerts an ionising action upon it.

In the *Actes* de la Société helvetique des Sciences naturelles (85me session 1902 à Genève), Prof. H. Ebert gives an account of the progress which has been made towards an explanation of the phenomena of atmospheric electricity on the "Elektronentheorie." He mentions some of the results of measurements,

made with his aspiration apparatus and by other methods, of the number of positive and negative ions present in atmospheric air under different conditions. The variations in the richness in ions of the air at different heights (studied by means of balloon observations) and the excess of positive ions in the air carried down by the Föhn are of special interest. The electrical phenomena accompanying precipitation are explained by the difference in the efficiency as condensation nuclei of the positive and negative ions. An attempt is made to treat this part of the subject quantitatively. The maintenance of the ordinary fine weather electric field is put down to the difference between the positive and negative ionic velocities.

Prof. J. A. McClelland has described in the Royal Dublin Society's *Transactions* (November) experiments upon ionisation in atmospheric air. These experiments are introductory to a study of the number of ions in the free air of the atmosphere under varying meteorological conditions. Like Prof. Ebert, he has obtained evidence from the results of preliminary experiments of a larger number of ions per c.c. of free atmospheric air than was shown by Prof. Rutherford's measurements in Canada. The latter found on some occasions no more ions per c.c. of the free air than are generally produced *per second* in each c.c. in air in closed vessels, whereas Prof. Ebert's results are more nearly what we should expect if the rate of production of ions in the free air were the same as in a closed vessel.

MEDICAL REPORT OF THE LOCAL GOVERNMENT BOARD.[1]

THE annual report issued by the Medical Department of the Local Government Board always contains matter of interest. The first half of the volume comprises an excellent summary of the contents by Dr. Power, the able head of the department, the vaccination and other statistics, and the reports of inquiries into the sanitary administration of various districts, of outbreaks of epidemic disease, and on the distribution of plague and cholera. There is a mass of information in these pages of the greatest value to the specialist.

But to the readers of NATURE the reports of the auxiliary scientific investigations carried out for the Board will prove of most interest. Dr. Klein is responsible for four of these :—(1) On the nature of the Haffkine plague prophylactic; (2) on the phenomenon of agglutination; (3) on the micro-pathology of hæmorrhagic small-pox; and (4) on the differentiation of the *Bacillus enteritidis sporogenes, B. butyricus*, and *B. cadaveris sporogenes* from one another. The cultural and other differences between these microbes are detailed, and may prove very useful in the bacteriological examination of potable waters. The *Bacillus aërogenes capsulatus* is here alluded to, but that is all. This organism is closely allied to, if not identical with, the *B. enteritidis sporogenes*, and it is hardly right that the work of the Americans in this connection should be dismissed in so summary a fashion.

Dr. Sidney Martin has once more taken up the investigation of the chemical pathology of infective diseases, dealing in this paper with the products of the *B. dysenteriae*. Experiments were performed in order to ascertain whether any toxic substance is produced when the bacillus is grown in fluid media. Indications of the presence of such a soluble toxin, proteid in nature, were obtained, but are not convincing, as no control experiments are mentioned; the most potent poison is certainly contained in the bacterial cells themselves.

Dr. Gordon contributes a useful paper on certain diphtheria-like organisms, and Dr. Houston reports on the inoculation of soil with sewage and on the examination of Chichester well water. Dr. Haldane gives further details of his method for destroying rats on shipboard with carbon monoxide, but this does not seem to be so convenient and safe as the Clayton process with sulphur dioxide.

The reports from the Board's vaccine department are of considerable interest. Nearly 1,000,000 charges of glycerinated calf lymph were supplied from the Board's laboratories during the year under review, and proved to be of excellent quality. Dr. Blaxall gives an account of an outbreak of equine variola, Mr. Fremlin describes a useful method for anaërobic cultivation, and Dr. Green discusses the action of various alcohols and other substances upon vaccine lymph. The volume is illustrated with several excellent photomicrographs.

R. T. HEWLETT.

[1] Thirty-first Annual Report of the Local Government Board, 1901–2. Supplement containing the Report of the Medical Officer for 1901–2. Price 6s. 9d.

HERBERT SPENCER.

BY the death of Herbert Spencer England has lost the most widely celebrated and influential of her sons. He has passed away in the fulness of years and honours, having lived to complete the great work that he designed and took in hand half a century ago. Spencer was not without honour in his own country, yet our national indifference to philosophy and to all systematic thinking, and the subserviency of a great part of our professed philosophers to the great German metaphysicians, have undoubtedly prevented his receiving from his countrymen during his lifetime the full measure of recognition that is due to his splendid services to science and philosophy. And, indeed, the enthusiastic and unstinted eulogy of our great dead, voiced by the Press of every civilised country during the past week, has brought home to many of us for the first time the greatness of the man who by sheer force of intellect and character has won the tribute of the world. For in Spencer's work there was nothing designed to attract the attention of the crowd, there was no attempt to write down to the level of the multitude; it was one long and steady effort of a great intellect systematically grappling with the great problems. Yet his books have been translated into a score of languages, have been studied by hundreds of thousands of serious men, and in no small number of them have aroused admiring and enthusiastic gratitude.

Spencer's system of philosophy was broadly distinguished from other latter-day systems, save in a measure from that of Comte, by two features; firstly, his conception of philosophy as the unification of the sciences; secondly, the evolutionary standpoint from which he sought to effect that unification. While the great metaphysicians have for the most part set out with the premise that the world must be intelligible to our minds, and have held it to be their business to present it as an intelligible whole, Spencer prefaced his system of philosophy with a demonstration of the irresolvable mystery that lies behind us and before, and sought merely to discover the most general laws or statements that will express the relations of all the phenomena that science has revealed. That towards this great work he has made splendid and enduring contributions no one will deny. That there remain great gaps in his system is equally undeniable, and the most serious charge that can be made against him is that he professed, or seemed to profess, to have bridged the chasm between the inorganic and the organic worlds, between the world of mechanism and the world of volition.

When Spencer is compared with other great thinkers, he stands distinguished by the immense range of his knowledge of the facts and principles of the sciences and by that wonderful power of generalising their laws which was the instrument by means of which he sought to unify them in one grand scheme of thought. It is true that the specialist may discover shortcomings in his treatment of each one of those sciences, not less in the psychology, in which he is acknowledged as a master both of principles and of details, than in his biology and sociology; and it is true that certain of his great generalisations, for example, the ancestral-ghost-theory of the origin of religions, cannot now be regarded as well founded. Nevertheless, he has contributed to each of these sciences a wealth of illuminating and suggestive ideas, and even those of his hypotheses that have proved untenable have done so great service in provoking thought and discussion that, had he given to the world these unsuccessful suggestions only, he would still have had a great claim upon our gratitude.

On contemplating the completed System of Synthetic Philosophy there is a certain pathos in the fact that the final volumes, to which Spencer had long looked forward as the consummation and crown of his life's labour, namely, those setting forth the principles of ethics, are perhaps generally felt to be the least convincing part of the whole, a feeling which, it can hardly be doubted, was shared by the great thinker himself. But, whatever may be the final verdict as to the value of Spencer's ethical philosophy, there can be no difference of opinion as to the great moral value of his own life. He gave us an example, all too rare and too sorely needed in these days, of a life strenuously devoted through all the years of maturity and age to the realisation of a great object, the spectacle of a man working on with steadfast purpose, unmoved alike by the neglect and by the acclamation of the world, "Voyaging through strange seas of thought, alone" towards the lofty heights of Thought whose dim and cloud-capped towers had caught and fixed his eager youthful gaze.

Spencer's writings may seem to some readers cold and lacking in emotional fervour, and the man himself a little wanting in human sympathies; but can it be doubted that so grand an effort was sustained throughout the arduous years by a deep feeling for the mystery and pathos of the life of man, that tiny organism endowed with the capacity for thought and set to wonder, to labour, and to hope among the spheres that roll for ever through infinite space?

If it could be ascertained what parts of all Spencer's work do, and will, appeal most deeply to great numbers of thinking men, they would probably be found to be, firstly, the demonstration of the Unknowable Mystery that must for ever elude our grasp as the bounds of knowledge are thrown ever wider and wider, and secondly, the doctrine of Transfigured Realism that gives to the mind, painfully halting between the vain imaginings of the pure idealists and the shallow teachings of the materialists, a firm and sane standing-ground from which to view the two great orders of being, the internal and the external worlds.

Much of Spencer's way of thinking and many of his ideas have become a part of the very atmosphere we breathe and cannot but accept, and much of his work must form a part of every future system of philosophy that shall attempt the unification of the sciences. His fame is secure, for posterity can never forget that in an age in which men's minds were oppressed, and in danger of being overwhelmed, by the rapidly growing wealth and complexity of their knowledge of the phenomenal world, Spencer generalised boldly and effectively, breathing life into the dead bones of science.

NOTES.

THREE Nobel prizes for science have been awarded as follows:—for physics, Prof. Henri Becquerel divided with M. and Mme. Curie; for chemistry, Prof. Arrhenius; and for medicine, Prof. Finsen. The formal distribution of the prizes took place on Thursday, December 10, in the presence of the King of Sweden and several members of the Royal family and a distinguished gathering. It is announced that Prof. Finsen has decided to give 50,000 kroner (2753*l*.) from the amount awarded to him to the Phototherapeutic Institute at Copenhagen, and that two members of the governing body will each present it with a like sum.

MR. BRUCE, the leader of the Scottish Antarctic Expedition, which was sent out last year on board the *Scotia*, has arrived at Montevideo from the Falkland Islands. He reports that all is well on the *Scotia*, which is on the way to Buenos Ayres. Six men have been left behind in charge of a meteorological station. The meteorological station referred to is evidently the station set up by Mr. Bruce at Cape Pembroke, Falkland Islands, before the *Scotia* left for the southern seas in January last.

IT is announced that Dr. Oscar Guttmann has presented to the Chemical Society a photograph of the portrait of Roger Bacon in possession of Lord Sackville at Knole House, Sevenoaks.

DR. HANS GADOW, F.R.S., has, we learn from *Science*, accepted an invitation of the Lowell Institute, Boston, to give a course of six lectures, beginning March 29, 1904, on "Coloration of Amphibians and Reptiles." Dr. Gadow will probably give other popular lectures on zoological subjects while he is in America.

IT is reported in *La Nature* that Baron Edmond de Rothschild has sent 20,000 francs to M. Albert Gaudry, president of the Paris Academy of Sciences, to make it possible for the Museum of Palæontology to secure the very precious specimens of the Filhol collection which were obtained from the Quercy phosphate beds.

ON November 28 about three hundred teachers met at New York to form an Association of Teachers of Mathematics in the Middle States and Maryland, the prime object of which is the improvement of mathematical teaching. Prof. David Smith, of the Teachers' College, was elected president of the Association; Prof. H. B. Fine, of Princeton University, vice-president; and Dr. Arthur Schultze, of the New York High School of Commerce, secretary. After President Butler, of Columbia University, had delivered the address of welcome, papers on various aspects of mathematical teaching were read by Mr. Harry English, of Washington, D.C., Mr. Isaac N. Failor, of Richmond Hill, Dr. Arthur Schultze, and Mr. J. L. Patterson, of Philadelphia. The next meeting of the Association will be held at Columbia University, New York City, about next Easter, and applications for membership and other communications may be addressed to Dr. Schultze, No. 4 West 91st Street, New York City.

HIS MAJESTY THE KING has presented a fine stag to the University College of North Wales for its zoological museum. The animal has been specially selected for the college collection, and will illustrate fully the characters of the red deer. Prof. White has had the stag sent to Mr. Edward Gerrard, of Camden Town, to be mounted. The following gifts have reached the college during the past few weeks:—Mr. Assheton-Smith, specimens of the guanaco, St Kilda sheep, Australian swan, goshawk, grouse, and rhea; Mr. Herbert C. Hodson and Mr. James M. Reid,

bloodhounds; Dr. Corbet W. Owen, nests of the African weaver bird; Mr. Hugh O. Hughes, specimen of guano from the Chincha Islands; Mr. H. S. Forrest, small collection of fishes, &c.; Mr. J. Pugh, a fine pike; the Rev. W. S. White, small collection of bird and bat skins. Prof. White has also received a second gift of 10*l*. from Mr. Henry R. Davies for the zoological museum.

THE annual dinner of the Institute of Chemistry was held on Monday night, with Mr. David Howard, the president, in the chair. The president, in responding to the toast of the Institute, proposed by Lord Justice Cozens Hardy, remarked that the application of chemistry in our industries was a national question. Most of the successful manufacturers in Germany whom he knew were doctors of philosophy and very well educated men, who had, in addition, devoted their lives to the study of every detail of their work. It must be realised in England that the technical chemist should be at least as well educated and thoughtful as his German friends. The Institute was now considering what could be done to direct the studies of men engaged in technical work, for, while his general training must not be diminished, a technical chemist could not have too high a scientific training. Mr. Haldane proposed the toast of "Prosperity to Science and to Scientific Industries." He remarked that as a nation we needed science. It was not that we were going back; the general average was higher than ever before, and it behoved us to see that we kept our place. We needed science in our Government, in our industries, in our education. The time, then, had surely come when more science should be instilled into national methods. Why should not the grants to the university colleges, and to colleges giving scientific teaching of a university type, be increased? Any Government would be glad to do that if it felt that there was something like organised public opinion at its back. Then we suffered in England from a want of enthusiasm for science on the part of our manufacturers, and little progress could be made until this was remedied.

A PAPER, entitled "The Metrical System of Weights and Measures," was read by Mr. Alex. Siemens at the Royal Statistical Society on Tuesday. The author expressed his conviction that, though scientific men had for some time previously been discussing the subject in a general way, there is little doubt that the present metrical system is the result of the agitation of James Watt, who took the subject up in the year 1783. The history of the question in this country was traced from the year 1824, when Parliament was first approached on the subject. Last year the Liverpool Cotton Association effected the change from the binary to the decimal system of quotation, and Mr. Siemens showed how practically useful the 2000 lb. ton and other forms of reckoning on the decimal system had proved in the United States and Canada, as, indeed, in many British dependencies. In France the metric system was not really legal to the exclusion of every other until January 1, 1840, that is to say, a little more than sixty years ago. To-day only one system of measures exists in that country, and it is absolutely incorrect to say that the old measures are still employed there; even their values are becoming more unknown. The only notable exception is to be found in those industries or trades in which foreign nations which have not adopted the metric system have such a preponderating influence as to, thus far, impose the use of their own measures. Even in Germany, where the metric system has been in use not much more than half as long as it has been in France, though a few old names of weights and measures are in use, they really denote metrical measures, and may be treated as local expressions only. As regards the expense of the change, Mr. Siemens denied the suggestion that our engineering machinery for screw cutting would have to be scrapped—all that would be necessary would be to buy suitable exchange wheels. The author finally expressed his opinion that not only our own dependencies, but other nations would follow our lead if we made the change, and that thus international unity of weights and measures would at once become an accomplished fact.

THE Bradshaw lecture was delivered before the Royal College of Surgeons on December 9 by Mr. Henry Morris, the subject being "Cancer and its Origin." An admirable survey of the various theories of the nature of cancer is given, such as the "lost balance theory" of Thiersch, adopted by some recent writers, *e.g.* Foulerton, the "tumour-germ theory" of Cohnheim, and the various parasitic theories. Mr. Morris does not look with favour upon the parasitic theories; he says, "neither fission fungus, yeast fungus, nor psorosperm—neither bacterium, blastomycete, nor protozoon—has up to the present moment been satisfactorily shown, in spite of years of patient study by many skilled workers, to be in any sort of causal relation to the disease." He believes that there is "one theory which is more consistent than any other with all that we know about malignant disease, which fully explains the origin of very many non-malignant tumours," this being Cohnheim's "tumour-germ theory," which states that tumours originate from a matrix of embryonic cells which during fœtal life are cut off from their proper connections. Mr. Morris discusses the evidence for and against this theory, and the practical outcome should it be proved to be true.

ANOTHER example of the practical utility of wireless telegraphy at sea was afforded the other day as a result of the accident which happened to the *Kroonland* on her way from Antwerp to New York. The steamer disabled her steering gear when west of the Fastnet and was obliged in consequence to abandon her journey. Not only was the captain able to communicate particulars of the accident at once to the agents of the American line at Antwerp and to receive (in less than an hour and a half) instructions as to how to proceed, but the passengers were enabled to send messages to their friends and relatives assuring them of their safety. A large number of passengers made use of the wireless telegraphy installation, some telegraphing for more money, which was wired to them per the purser. The wireless installation on the *Saxonia* was useful in another way a short time back; getting into communication with the *Campania*, the latter informed the *Saxonia* that berths were waiting for English-speaking emigrants as motor-men on the surface lines of New York. These two instances serve to show the benefits that wireless telegraphy confers on travellers by sea.

THE fourth report of the National Electric Light Association's committee for the photometry of arc lamps contains some interesting results of measurements of the light distribution and mean spherical candle-power of the American pattern Nernst lamps. These lamps are made with one, three, six or more glowers in parallel; the measurements of the committee were made on the first three of these types. They show that the light distribution below the horizontal is very good, but above it is very poor. The distribution in the horizontal plane is fair; thus with the six-glower lamp the maximum horizontal candle-power is 112, the minimum only about 40 candles; the mean horizontal candle-power is 85 candles. For the same lamp the

mean spherical candle-power is approximately 170 candles, and the mean hemispherical candle-power for the lower hemisphere 290 candles. The maximum candle-power is 400 candles in a direction vertically downwards. It will therefore be seen that the efficiency varies very greatly according to the direction in which the candle-power is measured. Taking the mean spherical candle-power, which is the only value of any use for comparative measurements, the consumption of power comes out to 3·3 watts per candle; for the mean hemispherical it is 1·9, and for the mean horizontal 6·6 watts per candle. If, however, the measurement be made in the direction of maximum candle-power, the consumption of power is only 1·3 watts per candle. The general distribution of the light and the values of the mean and maximum candle-powers show that this lamp is on a par with a small (six to eight ampere) arc as a source of illumination.

We have received further copies of the *Journal* of the Meteorological Society of Japan (for September and October last), containing papers on the climatology of Formosa and other important subjects relating chiefly to Japanese meteorology. The articles are all in Japanese, but the promise of issuing some in European languages is reiterated. We look forward with pleasure to the fulfilment of the promise, as the proceedings of this energetic society will doubtless be of much interest to our readers.

The weather for the present month is proving very disappointing, and, after a few days with somewhat low temperatures at the commencement, the conditions have again become cyclonic with the usually accompanying mild and damp south-westerly winds blowing from off the relatively warm waters of the Atlantic. Disturbances are again reaching us with considerable frequency, and the rains which are occurring over the whole country are considerably augmenting the already excessive falls for the present year. At Greenwich the fall for 1903 is now approximately 35 inches, and is about an inch in excess of any previous annual record during the last sixty years. The storm areas which have arrived over us recently have had the barometer as low as 29 inches, and gales have been experienced at many places in exposed positions on our coasts.

A correspondent sends us an extract from a letter describing an aurora observed at Calgary, Canada, on October 31, when auroral displays were seen in many parts of the world (see this vol. p. 9). At Calgary a peculiar light was noticed in the sky about 6.30 p.m. Large and beautiful vertical shafts of coloured light were first seen moving about the sky. "Presently the shafts began to lower, vastly increased in size and number, until their lower tips touched the ground (objects about half a mile off could be seen through them) and the upper tips met in the zenith, losing themselves among the stars directly overhead. They formed a perfect apse, bright ruby above, and coming through purple and greenish tints to gold at the bottom. The apse shivered and shook out all sorts of colours, and literally chased me in the buggy, the nearer huge shafts being but a few yards off. A horse in a field alongside tore madly round in terror. A few minutes later there were only a few stray but grand shafts left."

Some experiments on the influence of a magnetic field on a tuning fork are described by Mr. O. Kirstein in the *Physikalische Zeitschrift*, and lead to the results that if the lines of force are perpendicular to the plane the frequency is increased; if parallel it is diminished; at an angle of 45° no change occurs; the decrease in the second case is greater than the increase in the first; the changes are in every case proportional to the field, and the action of the magnetism is only temporary. These results, some of which agree with previous investigations, have an important practical application in connection with electrically excited tuning forks.

The frequent use of silk suspension fibres in physical laboratories renders the determination of the elastic constants of silk a problem of considerable interest. This problem forms the subject of a paper by M. F. Beaulard in the *Journal de Physique*, in which hysteresis curves are drawn showing the elongations produced by traction. The most remarkable conclusions drawn are, firstly, that the curve ultimately tends to become a straight line, the hysteresis then vanishing; and, secondly, that the value of Poisson's ratio, calculated from observations of the behaviour of the fibre under traction and torsion, is about 1·56, and this high value supports the view that silk is not isotropic.

A graceful tribute to the venerable Japanese botanist, Ito Keisuki, is paid by Mr. Botting Hemsley by the establishment of a new genus of the Bixineæ under the name Itoa. Dr. Tokutaro Ito, who is associated with his grandfather in the compliment, has followed in the paths of his illustrious ancestor in his systematic contribution entitled "Plantæ Sinenses Yoshianæ."

In 1894 Prof. Carmody published a summary of the industrial resources of the island of Trinidad, and in a small pamphlet recently issued he uses this as a basis of comparison with the conditions and general trade returns of the island for the year 1902–3. The principal export, sugar and sugar products, has, of course, decreased considerably, but there is a balancing increase in the amount of cacao. Another important product is that of asphalt, which has also steadily increased in amount. A striking feature of the statistics is the rising value of imports from Canada.

The Barbados *Agricultural Reporter* of November 18 contains a report of a meeting of the Legislative Council of the island at which it was resolved to offer rewards for the destruction of mongooses. With this, it may be hoped, we shall soon hear the last of an ill-starred experiment in acclimatisation.

A circular has recently been issued by Messrs. Stejneger and Miller, the well-known American naturalists, urging the governing body of the Carnegie Institution to undertake a thorough and detailed biological survey of the eastern Holarctic region, on the plan followed by Dr. C. H. Merriam in the United States. Despite the gigantic nature of this undertaking, it is estimated that it might be completed within ten years.

Among several other articles in the *Journal* of the Quekett Microscopical Club for November, we may refer to one by Mr. W. H. Harris on the emission of musical notes by the hover-flies of the genus Eristalis, and on the habit from which they take their name. It appears that the thoracic spiracles of these insects carry a couple of crescentic chitinous rods joined by a ligament, so as to form a bow. A large bundle of muscles is attached to these rods, which supports a number of delicate membranes pleated in a complex manner. The air-chamber is kept inflated by the movements of the fly, and the musical notes are apparently produced by bringing the pleated edges of the membranes close together and expelling, by muscular action, the air from the chamber with sufficient force to set them vibrating.

We have received from Mr. E. B. Waggett a communication with reference to a proposed method of graphically indicating the duration of the residence in the British Islands of the various members of the bird-fauna. On a sheet of ruled paper two large dots, an inch apart, are marked on four of the ruled lines, the dot on the left indicating New Year's Day, and the one on the right December 31. In the case of permanent residents, the two dots are connected by a line. Winter visitors are indicated by drawing a line half an inch long on each side of the right dot, the extremities of these lines being marked above by arrow-heads, of which the one on the left points downwards, to indicate a southern migration, while that on the right points in the opposite direction, and thus implies a northern flight. Summer visitors, on the other hand, are indicated by a half-inch line midway between the two dots, with arrows on the lower side of the extremities, the direction of which indicates the migration. Species which merely rest for a short time in Great Britain during the spring and autumn migrations are indicated by drawing two quarter-inch lines some distance on each side of the right dot, with an arrow both above and below each to mark the direction of the migration. Modifications of these may be easily drawn to indicate residents which build twice, or even thrice, in a season, and also resident species building in the spring which are reinforced in autumn by migrants from the north for the winter season.

In the January number of the *Psychological Review* the tenth anniversary of the journal will be celebrated by the founding of a special literary section, to be published monthly, in which fresh, prompt treatment will be given to the literature of psychology, philosophy, and cognate subjects.

Messrs. J. and A. Churchill have now published separately the second part of "Elementary Practical Chemistry," by Dr. Frank Clowes and Mr. J. B. Coleman. The present publication is divided into three sections, dealing respectively with qualitative, volumetric, and gravimetric analysis.

The Huxley lecture for 1903, by Prof. Karl Pearson, F.R.S., "On the Inheritance of the Mental and Moral Characters in Man, and its Comparison with the Inheritance of the Physical Characters," has now been published separately by the Anthropological Institute. It will be remembered that we published an abstract of Prof. Pearson's lecture in our issue for October 22.

Mr. W. C. Fletcher, head master of the Liverpool Institute, has been appointed to the newly-established post of chief inspector of secondary schools. Mr. C. A. Buckmaster, acting senior chief inspector at South Kensington, has been appointed chief inspector of schools under the branch of the Board of Education which deals with evening schools, technology, and higher education in science and art.

The fourth volume of the "*Knowledge* Diary and Scientific Handbook" has now been published, and in this 1904 issue there is much information which will prove of use to men of science. Among many interesting contents may be noticed the numerous practical articles, which include one by Mr. William Marriott on practical meteorology, and one by Mr. Edwin Edser on the optical constants of lens combinations. The tables, too, are abundant and well selected.

We have received a copy of Prof. Robert Wallace's opening lecture of the session on October 13 to the students of the department of agriculture and rural economy at the University of Edinburgh. The lecture is entitled "Agriculture, Live Stock, and Dairying in Argentina," and deals with Prof. Wallace's observations and inquiries during his recent six months' tour in South America. The booklet is published by Messrs. Oliver and Boyd at ninepence.

The issue of "Who's Who" for 1904 contains above one hundred and fifty pages more than that for 1903, and the increase in size indicates the large number of additional biographies now included. The notable persons whose biographies are given are not exclusively British, for particulars are provided also of American men and women of eminence. Messrs. A. and C. Black are to be congratulated upon the general appearance of the book, and the editor upon the excellence of its arrangement. The price of the 1904 edition is 7*s*. 6*d*. net.

Many of our readers are acquainted with those excellent volumes of "Photograms" (Messrs. Dawbarn and Ward, Ltd., London) which have appeared yearly since 1895. The issue for the present year surpasses, if possible, the high standard which this publication had reached, and our photographic readers will find in these pages much that will be of interest. As a pictorial and literary record of the artistic photographic work of the year the compilers and publishers are to be congratulated, for the volume is high-class in every respect.

The first number, that for November, of the *Central*, a magazine edited on behalf of the City and Guilds of London Central Technical College Old Students' Association by Dr. E. F. Armstrong and Mr. Maurice Solomon, is an excellent performance. It is attractively produced, well illustrated, and interestingly written. There is an instructive article on oscillographs by Mr. Solomon, a description of the new electrical laboratories by Mr. Joseph Griffin, and an unusually large number of notes concerning the work and doings of old students; one section of these notes, dealing with chemical research, is conclusive evidence that the atmosphere of the Central Technical College is favourable for the development of investigators; and the new magazine shows that literary as well as scientific enterprise is encouraged.

In a paper read recently before the Church Society for the Promotion of Kindness to Animals, the Hon. Chas. S. Rolls remarked that at the present time those who were seeking to develop motors and motoring were experiencing exactly the same opposition from many rural communities as the promoters of railways met with earlier. Having disposed of many thoughtless and amusing objections brought against motor vehicles by opponents, he remarked that, as regards other objections, it should be remembered that the difficulties of noise, vibration, smell, and untrustworthiness must eventually be, and are rapidly being, overcome. This country has, said Mr. Rolls, been infested with a host of inferior cars, consequently these objections have been more apparent here than they are on the Continent or in America. The introduction of the motor-car will, undoubtedly, constitute the means of better intercommunication, which has always been the chief factor of civilisation. It will result, too, in the decrease of wear and tear on the roads, greater economy of space in the streets, and especially a greatly increased cleanliness of the latter.

The additions to the Zoological Society's Gardens during the past week include a Brown Capuchin (*Cebus fatuellus*) from Guiana, presented by Mr. F. J. Holmes; two Tantalus Monkeys (*Cercopithecus tantalus*) from West Africa, a Globose Curassow (*Crax globicera*) from Central America, two Brazilian Tanagers (*Ramphocoelus brasilius*) from Brazil, a Tytler's Parrakeet (*Palaeornis tytleri*) from the Andaman Islands, deposited.

OUR ASTRONOMICAL COLUMN.

THE TOTAL SOLAR ECLIPSE OF MAY, 1900.—The report of the expedition organised by a joint committee of the Royal Dublin Society and the Royal Irish Academy to observe the total solar eclipse of May, 1900, has just been published in vol. viii. (series ii.) of the *Scientific Transactions* of the Royal Dublin Society.

The instruments used were chiefly lent by Sir Howard Grubb and Mr. W. E. Wilson, F.R.S., who, with Prof. Joly, Dr. A. A. Rambaut and others, were members of the expedition. They included two cœlostats and two coronagraphs, one of the latter being of 4 inches aperture and 19 feet 4 inches focal length, the other of 6 inches aperture and 7 feet 10½ inches focal length; a special spectroscopic apparatus for securing a continuous series of photographs of the spectrum of the chromosphere was also taken. The second of the two coronagraphs was used with a coloured screen, made by "fixing" an ordinary unexposed film, and then soaking it in a bath of tartrazine, which allowed only the green light about the chief coronal radiation to be photographed. The resulting negative, which was exposed for eighty seconds, shows considerable extension of the outer corona, although the spectroscopic observations indicated that the green corona line was very faint during this eclipse.

The spectra were obtained with a kinematograph especially designed by Sir Howard Grubb to take twelve plates at the second and twelve at the third contact, in such a manner that no interval occurred between two successive exposures, the idea being to observe whether all the bright lines appeared or disappeared simultaneously, or whether some became reversed earlier than others as would be expected if their respective absorptions took place at different levels. It was found that the lines generally disappeared in the order of brightness shown on the original spectrum, although there were several exceptions to this rule, notably the strontium lines at λ 4078 and λ 4216, which disappeared earlier than other lines of the same original intensity. These differences are shown in the analytical table which accompanies Dr. Rambaut's discussion of the spectra. The wave-lengths and origins given in this table seem less determinate than those which have been previously published by other observers. Several plates showing reproductions of the corona photographs, which have been discussed by Mr. Wesley, and of the spectra are given at the end of the paper.

CLOUDS ON MARS.—An article by Mr. Denning, published in the December number of the *Bulletin* de la Société astronomique de France, records the appearance of cloud-like formations on Mars during the latter half of May. On May 19 and 21 the Syrtis Major was dark and sharply defined, but on the latter date a brilliant region appeared over its southern extremity, whilst on May 23 this region was very faint and ill-defined, although other features usually less obvious were plainly seen. Mr. Denning describes the region as appearing to be covered by strongly reflecting vapours which were not dense enough to hide completely the surface, but were sufficiently dense to give it a more luminous and less definite appearance. On May 25 and 27 a luminous zone was observed to the north of the Mare Cimmerium, and during the latter part of the month an extensive luminous band was visible along the northern edge of this sea, Syrtis Major, and the Linus Sabæus. It seems probable to Mr. Denning that the clouds of white vapour which were observed on the eastern edge, south of Syrtis Major, on May 21 travelled very rapidly in a northern direction, and thus caused the lack of definition observed in the above regions on the later dates, and he connects this phenomenon with the appearance of a white projection observed by Mr. Lowell, at Flagstaff, on May 26.

Several other remarkable phenomena, notably a marked division of Nilus by a bright spot, which extended far to the south-east from the eastern edge of the Lunæ Lacus, on May 4, were observed by Mr. Denning, and, on analysing his observations, he arrives at the conclusion that *real* changes do present themselves in the details of several Martian features, although many of them may be only temporary and due to atmospheric causes.

As regards the question of Martian canals, Mr. Denning states that there is no doubt as to the objective reality of the streaked and striated appearance of the northern hemisphere, and to him the canals appear not as straight and narrow lines, but as currents of dark material with frequent condensations having the appearance of a natural rather than an artificial origin.

SEISMOLOGICAL NOTES.

THE fourteenth number of the *Publications* in European languages issued by the Earthquake Investigation Committee of Japan is entirely devoted to a profusely illustrated paper on the modulus of rigidity of rocks, by Mr. S. Kusakabe. The experiments, which are a continuation of investigations made by Prof. H. Nagaoka on the elastic constants of rocks, relate entirely to torsion, and show, amongst other things, that even for very small strains Hooke's law does not hold, that in the relationship of stress to strain, or twisting couple to twist produced, rocks exhibit a marked *hysteresis,* and that the modulus of rigidity of a rock in its virgin state is greater than is usually supposed. Inferences to be drawn from these important investigations (in which stresses are applied *slowly*) are that waves of small amplitude are propagated with a higher speed than those with a large amplitude (increase an amplitude ten times and the velocity is reduced to half or one-third), also in a strained medium, as for example, along a mountain chain, velocity is somewhat increased. In view of the first of these inferences, Mr. Kusakabe does not see the necessity to assume that the tremors of an earthquake follow paths different from that of the large waves or shocks. Whether we agree or disagree with this suggestion, we can congratulate the author on his important memoir, which is a new leaf in seismometrical research.

Amongst other recent publications relating to earthquakes we have before us Nos. 13 and 14 of the new series of *Mitteilungen* issued by the commission appointed by the Vienna Academy of Sciences for seismological investigations.

The first of these, by Dr. R. Hoernes, gives an account of the earthquake which, on July 5, 1902, resulted in considerable destruction along a line to the east of Saloniki, and fairly parallel with the Vardar River. This is a fault line along which there are hot and other springs. From the fact that these became muddy, altered in temperature and in volume, whilst new springs were created, as at Güvezne, the inference is that the earthquake was accompanied by subterranean rearrangements of strata. A discussion of the movements along this and other fault lines in Macedonia, and of changes in level which are apparently in progress at Saloniki and its neighbourhood, leads to the conclusion that hypogenic geological processes have in this part of the world a marked activity.

The second communication, from Prof. Dr. W. Láska, is on the determination of the distance of earthquake origins from observing stations by means of seismograms. That the differences in time between the arrival of various phases of earthquake motion vary with the distance an earthquake has travelled is a fact which has received application for many years. In the reports of the Seismological Investigation Committee of the British Association (1900 and 1902), by means of curves the relationship between the time intervals and distances is expressed geometrically. Dr. Láska gives similar information by means of tables. From observations made at three stations he also gives equations the solution of which leads to the determination of a latitude and longitude for an epicentrum. In the British Association report for 1900 simpler and more certain solutions are given for the same problem.

In No. 15 of the same *Publications* Dr. Eduard Mazelle gives the results of his investigations respecting the connection between microseismical pendulum movements, the wind, barometric pressure, the state of the ocean, and other natural phenomena. The results at which the author arrives confirm the results from similar analyses made many years ago in Japan, and to be found in the *Transactions* of the Seismological Society of that country and in the reports of the British Association. We are told that it is difficult to find a direct connection between tremors and atmospheric

pressure. Tremors occur most frequently, but by no means always, with marked changes in pressure. An observation more novel in its character is that days when pendulums were much disturbed in Trieste coincided with corresponding disturbances in Strassburg. It is apparently taken for granted that the tremors recorded have a seismic origin.

In No. 16 Dr. J. Knett publishes a list of 507 shocks which were recorded between February 13 and May 6 in north-west Bohemia, which he follows in No. 18 by an account of an earthquake which on November 26, 1902, disturbed the same country.

No. 17, by Adolf Faidiga, is a lengthy description of the earthquake which, on July 2, 1898, created considerable destruction on the coast of Dalmatia, the vibrations from which reached Great Britain. It is largely of local interest.

In Nos. 2 and 3 of vol. ix. of the *Bolletino Della Societa Sismologica Italiana*, the well-known earthquake register published by this body is brought up to March 5, 1902. This is supplemented by two papers. In No. 2 Dr. A. Ricco adds to the knowledge we possess respecting the crater of Etna, and changes which are taking place in the same. On August 23, 1900, the interior of the crater was described and photographed. Its depth was then 282 m. On July 21, 1903, it was again photographed, and its depth was found to be 490 m. The supplementary contribution to No. 3, by S. Costanzo, is on the relationship or want of relationship between the wind and tromometric movements. The author apparently holds with Bertelli and others that the pendulum movements have an endogenous origin, and are not produced by the wind, but that they accompany, precede, or follow falls in barometric pressure. Dr. Agamennone regards the movements in question as being in great measure influenced by the wind. Our own experience, which is detailed in the *Transactions* of the Seismological Society of Japan, reports to the British Association, and in other works, is that vertical or horizontal pendulums, chemical balances, and like apparatus are set in movement when there is a marked fall in barometric pressure, a steep barometric gradient, or a marked fall in temperature; the movements more frequently occur during the night and in winter than during the day and in summer, and they may or may not occur with heavy gales. Instruments in a close atmosphere, as, for example, in a cellar, are more likely to be disturbed than similar installations in a well ventilated or even draughty room. Burning a lamp or a gas jet in a room frequently brings so-called microseismic storms to an end, and what occurs and creates annoyance in one room may not be observed in a neighbouring apartment.

In vol. ii. of the reports of the Mathematical-Physical Society of Tokio, amongst forty-seven papers which for the most part are mathematical we find five by Dr. F. Ōmori and one by Mr. A. Imamura which relate to seismology. The former of these contributions may, to a large extent, be regarded as epitomised reproductions of papers previously published by the Tokio Earthquake Investigation Committee, which we have already noticed (NATURE, April 30, July 9, 1903). In a note on the seismograms of distant earthquakes, Dr. Omori tells us that the "motion consists of a series of different epochs, in each of which the period remains essentially constant, while the amplitude, on the whole, is also constant, except for the occurrence of maximum and minimum groups." In a table we find ten groups, in which the periods vary between 1·02 and 66 second. After discussing the amplitudes and durations of these various phases, it is shown that the arcual velocities vary between 2 and 11·3 km. per second; as the result of more accurate work, this last quantity is now raised to 14·1 km. per second. One argument in favour of the supposition that the preliminary tremors and other phases of earthquake motion follow arcual paths is that the durations of these successive phases are proportional to the arcual distances they have travelled, and these durations are approximately equal to each other. The speeds for certain earthquakes were determined by dividing the difference of the distances of Tokio and certain European stations from an origin by the difference of the times of the arrival of seismic waves in Tokio and Europe. This, it must be observed, involves the idea that the velocity of preliminary tremors on short paths or on long paths is equal. Lastly, it is assumed that each phase recorded at a distant station originated simultaneously at the earthquake origin.

The results to which we are led by assumptions of this nature are well illustrated in the paper, "Notes on Milne Horizontal Pendulum Seismograms," by Mr. A. Imamura. In this paper records of the Guatemala earthquake of April 19, 1902, as published in circular No. 6 by the Seismological Investigation Committee of the British Association, are analysed. One result is to show that the preliminary tremors had an arcual velocity of 15·6, whilst the eighth phase of motion had only a velocity of 2·1 km. per second. These determinations, amongst other things, depend upon the time at which this earthquake originated, which Mr. Rockstroh, in Guatemala, gives as 2·27 a.m. G.M.T. This, it must be observed, apparently depends upon a single observation made at some distance from the epicentre. As being more probably correct, Mr. Imamura adopts 2.26 a.m. as the time of origin. Curiously enough, the determination of the exact time at which this particular disturbance took place became a matter to be considered by the law. At or about the time of the earthquake a certain block of buildings insured against fire, but not, as was stipulated in the policy, against fire occasioned by an earthquake, was burned down. The owners of the block claimed that the destruction was occasioned by the overturning of a lamp immediately before the earthquake, and if this were the case, the loss naturally fell upon the insurance company. The result was that a careful inquiry was instituted to determine the time when Quezaltenango and other cities were wrecked, and, so far as the writer knows, the time given for this occurrence was 2h. 21m. or 2h. 22m., which is a time that falls in line with what we know of earthquake speeds, and the times at which this earthquake was recorded at stations cooperating with the British Association in North America and round the Atlantic. If this latter time is fairly correct, and we therefore add 4 or 5 minutes to the time ordinates given by Mr. Imamura, we see that the times for transit of the first phase of earthquake motion are *not* proportional to arcual distances. The speed over short paths is less than it is over long paths. When we look at phase 8, which occurs about twenty minutes after the maximum, and see the many phases which follow, we do not see the reason why the transit velocity of phase 9, or even of phase 20, should not have been considered.

Following the maximum, as an earthquake dies there is almost invariably a series of fairly rhythmical impulses which gradually grow less in amplitude. These are separated by intervals of from two to five minutes, and may extend over two or three hours. Inasmuch as these phenomena may be observed equally well near to an earthquake origin as at a distance from the same, it would be unreasonable to suppose that if we were at a short distance from a centrum the movements last recorded there had been two or three hours longer on their journey than those first recorded. In rocky materials waves of small amplitude may travel more quickly than those of larger amplitudes; in an earthquake there may be ripples due to surface tension together with the more pronounced compressional, distortional, and gravitational waves, all of which may originate at practically the same time, but if we consider this to be the case for the followers of the main portion of a seismic disturbance, we are led to conclusions apparently unacceptable. The fairly uniform time spacing between the expiring efforts of an earthquake as recorded at a distance from an origin or near to the same, rather than leading to the conclusion that paths are arcual, suggests a rhythmical series of surgings possibly due to interferences or reflections at or near a centrum. A collapse takes place and a mass is launched upon some substratum. Each has its natural period, and when these coincide, it seems possible that at approximately equally spaced intervals a more vigorous set of waves starts out and adds to the train of its predecessors.

The first response to the primary disturbance may be the well-known *Uri Kaishi*, or return shaking, whilst its followers, which die down rapidly in amplitude, like the swinging of a damped pendulum, resemble a family series, children with children's children decreasing in vigour, not born simultaneously, but successively.

The general criticisms on the behaviour of the Milne horizontal pendulum are made without any reference to the

object for which it was installed, which was to determine "the times at which various phases of motion are recorded" (see British Association Reports, 1897, p. 130. Copy of a circular sent to foreign Governments and colonies). This it does, and a little more. If an observer desires to have an open diagram, he must employ clockwork to drive the record receiving surface at a higher speed, whilst a longer period than the one usually employed can be obtained by adjustment. It must, however, be remembered that the period obtained at one station may, on account of the wandering of the pendulum and "tremors," be unpractical at another, and that difference in adjustment at different stations destroys uniformity. Although with the object of stimulating further research we have criticised certain portions of the work before us, the bulk of it commands the admiration and thanks of all seismologists.

THE GILBERT TERCENTENARY.

THE tenth of this month was the three hundredth anniversary of the death of Dr. William Gilbert, the celebrated Elizabethan philosopher who laid the foundations of the science of electricity. The occasion was celebrated on Thursday, December 10, at the meeting of the Institution of Electrical Engineers by the presentation of a picture by the Institution to the town of Colchester, in which place Gilbert was born and died. The picture was painted by Mr. Ackland Hood; it is a fine historical painting representing Dr. Gilbert showing his electrical experiments to Queen Elizabeth.

The proceedings were opened by the president of the Institution with a short speech. Prof. S. P. Thompson then gave a brief address, in which he outlined Gilbert's life and his contributions to science. Gilbert was born in Colchester in 1544, and was educated at the school there and subsequently at St. John's College, Cambridge, at which he became mathematical examiner and senior bursar. He took the degree of M.D. in 1569, and rapidly advanced in the profession, becoming in 1599 president of the Royal College of Physicians, and a year later physician to the Queen. He died at Colchester on December 10, 1603, and was buried there in the Church of Holy Trinity. Eminent as he was as a physician, his claim to immortality rests not on his work in medicine, but on his pioneering investigation in the then almost non-existing sciences of magnetism and electricity. To him we owe the science of terrestrial magnetism; by numerous and careful experiments upon the loadstone he discovered many of the most important principles of magnetism, such as the existence of a magnetic field—an "orbe of virtue"—around the magnet, the screening effect of iron, and the destroying effect of heat. From experiments on a globular loadstone he was able to evolve the theory that the earth is itself a great magnet. Thus many years before Bacon, who is usually regarded as the father of the inductive method, Gilbert was using this method with signal success.

Gilbert's contributions to electricity are contained in the second chapter of Book ii. of the celebrated "De Magnete." He showed that not amber alone, but many other bodies, which he put in a class called *electrics*, can attract solid bodies when rubbed; that they attract everything, not merely straws or chaff; that damp weather hinders the electrification; and that a flame destroys it, as well as many other important facts which are now the fundamental principles of the science. He invented the electroscope, and discovered that the force of attraction is in a straight line towards the electrified body. From these simple beginnings has been gradually evolved in 300 years the immense structure of pure and applied electricity.

The Mayor of Colchester thanked the Institution for its gift in a brief and humorous speech. Amongst many other distinguished men present at the meeting were Sir W. Huggins, president of the Royal Society; Sir Dyce Duckworth, treasurer of the Royal College of Physicians, an office twice held by Dr. Gilbert; Prof. J. Larmor, representing St. John's College, Cambridge; the Mayor of Westminster; and Mr. Ackland Hood, the painter of the picture.

AGRICULTURAL NOTES.

THE third report on the Woburn Experimental Fruit Farm, recently issued by the Duke of Bedford and Mr. Spencer Pickering, F.R.S., is devoted to a discussion of the effects of grass on apple trees. In previous reports it was shown that grasses prove most injurious to young apple trees, and the experiments described here were designed to throw light on the causes of injury. Up to the present time the cause, or causes, have not been discovered, but the experimenters have made considerable progress, for they have shown that their first suspicions were unfounded. Grasses might reasonably be expected to injure young fruit trees by interfering with their air, or water, or food supply, but the careful experiments recorded in the report indicate that interference with air, water, and food has little or nothing to do with the question, and that the injury "must, in all probability, be attributed to the action of some product, direct or indirect, of grass growth which exercises an actively poisonous effect on the roots of the tree." This conclusion is based partly on the negative evidence of the experiments, in which the supplies of food, air, and water were controlled, and partly on the appearance of the trees grown in grass. These trees were always very sharply marked off from the others by peculiar tints of leaf and fruit, quite unlike those due to starvation, and produced obviously by some unhealthy condition of soil. The effects of grass on apple trees have been studied only on the shallow clay soil of the Woburn Fruit Farm and on a clay soil at Harpenden, and it is possible, as the experimenters are careful to point out, that on a richer soil, and in a different climate, grass might not prove injurious, but the Woburn experiments clearly indicate that horticulturists should avoid planting apples in grass, unless there is local evidence that grass does not injure the young trees.

In their work on apple trees the Duke of Bedford and Mr. Pickering are dealing with a special and well-marked case of a general problem of great interest to agriculturists—the effects of crops and of crop residues on the quality of soil. Every observant cultivator knows that land may get "sick" or "over-cropped" when a plant is grown too often, and he also finds that certain plants "exhaust" the soil in a peculiar degree for certain other plants. He has been told that this is a "food" or a "special food" question, and that interference with the air, food, and water supply explains all the ills which plants may suffer from competition with their fellows. At the same time, he does not feel satisfied that such phenomena as the disappearance of clover from land, or the effects of rye-grass on wheat are due to straightforward competition, and the "poison" theory of the Woburn experimenters will arrest his attention. Seventy years ago agriculturists were discussing De Candolle's "excretory theory," and found in it the chief explanation of the benefits due to a rotation of crops; when the theory was abandoned the facts from which it originated were forgotten, and in connection with the effects of grass roots on apple trees the following sentence from De Candolle is worth recalling:—"Thus we know that the thistle is injurious to oats, the Euphorbia and Scabiosa to flax, the *Inula betulina* to the carrot, the *Erigeron acre* and tares to wheat, &c." Though the plant does not "excrete," it may readily influence the character and condition of the soil either directly by the decomposition of its roots, or indirectly through its effect on soil organisms, and the Woburn experiments, which deal with this subject, will be closely followed.

In a paper entitled "Recherches sur la Synthèse des Substances Albuminoides par les Végétaux," MM. Laurent and Marchal, of the State Agricultural Institute, Gembloux, give a useful *résumé* of the sources of nitrogen to plants. In doing so they point out that during the latter half of the nineteenth century there was a tendency to overlook the importance of ammoniacal compounds, and to regard nitrates as the only sources of nitrogen to the higher plants. While nitrates are of chief importance, there are many plants, even colonies of plants, such as forest trees and the vegetation of marshes, that must depend largely or entirely on compounds of ammonia for the supply of nitrogen. The authors describe experiments on cress, white mustard, chicory, asparagus, white melilot, Persian lilac, and tobacco, and among other conclusions state that sun-

light is necessary for the synthesis of albuminoids in the higher green plants, and probably in all green plants, but that amides are produced in limited quantities in darkness and in parts of the plants which contain no chlorophyll. The lower plants devoid of chlorophyll can manufacture albuminoids in darkness, the necessary energy in this case being derived from the decomposition of organic compounds.

The twenty-third volume of the *Agricultural Journal* of the Cape of Good Hope is now being published in monthly parts by the Department of Agriculture, Cape Town. Though not new, the *Journal* has recently altered and improved its form, and this sixpenny monthly may be commended to the notice of all who are interested in the agriculture of South Africa. Prospective settlers would find many useful hints in it, for by means of editorial notes, special articles, and correspondence the *Journal* gives a clear presentation of the condition of the various farming industries of Cape Colony. Diseases of live stock are very common in the colony, and young men preparing for life on a South African farm should endeavour to gain some knowledge of veterinary hygiene before going abroad. The *Journal* usually devotes one or two articles in each number to veterinary subjects and the ailments of stock bulk largely in the correspondence columns. A correspondent from Aliwal North, writing in the October number, makes an observation which is interesting in view of the importance of ticks as carriers of disease germs. He reports that he had a flock of goats badly infected, but "happened to drop" on a cure in the shape of wild garlic. He gave the affected animals a small quantity; the ticks were not killed, but they dropped off the goats, and no further loss was suffered. Next year, when the tick season came round, the goats escaped injury.

Regulations for the purpose of preventing the importation of plant pests have been in force in Cape Colony for a number of years, but experience has shown greater caution to be necessary, and after January 1, 1904, new and stringent regulations will come into force. With the view of preventing inconvenience and loss to exporters, wide publication has been given to the altered regulations. The following points are of special interest to horticulturists:—(1) All plants or parts of plants not grown in South Africa must in future be sent to Cape Colony by sea. Imported plants must not be sent overland from other colonies. (2) Certain plants are absolutely prohibited, as, for example, stone-fruits from the U.S.A. and Canada, and peaches from any foreign country. (3) Permits are granted for the importation of small quantities of fruit trees from most countries, so that stocks of new varieties may be worked up in the colony. (4) Plants will be examined on landing by a competent officer, thus minimising the risk of importing pests. Trees and woody plants will be fumigated, the expense of fumigation being borne by the consignee. Any plants or parts of plants on which the examining officer finds a specially dangerous pest will be destroyed without delay.

BUDDHISM.[1]

THE appearance of the first number of a new quarterly magazine entitled *Buddhism* is an event of some significance, for it argues that the modern tendency of western inquiry into the ethics of this ancient eastern faith is sufficiently active to justify a commercial venture.

The object of the review is stated to be, first, to set before the world the true principles of the Buddhist religion; secondly, to promote certain humanitarian activities enjoined by Buddhist precept; and, thirdly, to unite, "as by a common bond of mutual interest and brotherhood, the many associations with Buddhist aims which now exist."

These objects are well sustained in the initial number of the review. It opens, most appropriately, with a poem by Sir Edwin Arnold, whose "Light of Asia" has probably done more to popularise Buddhism in the west than any literary effort hitherto known. It continues with a series of essays by Buddhist writers, in which the doctrines of Buddhism are explained and advocated with much earnestness, and, on the whole, with an intelligent appreciation of the limitations of ordinary human understanding; and it includes notes and references which sufficiently prove what an active agency in the practical world Buddhism is becoming. Amongst the notes is an invitation to western students to join the great brotherhood of the Yellow Robe, with a very explicit statement of the conditions under which candidates will be accepted. "Bhikkus of occidental nationalities" are first invited, "who in due time would be able to return to their own countries, there to spread the knowledge of Buddhism"—in short, missionaries. Amongst these Bhikkus there may be some who may be willing to take the Robe, but they are candidly warned that the conditions of life in the order are "somewhat severe for occidentals."

All this is practical business, and it leaves an impression that the review fills a space in the ranks of modern Oriental literature which is distinctly open to enterprise.

The article on the "Faith of the Future," coupled with that on "Nibbana" (Nirvana), is a clear and intelligible exposition of the gospel of law and self-culture inculcated by Buddhism, and is, perhaps, a clearer analysis of the final conditions of nebulous existence which crowns and completes the strenuous life of the Buddhist than can be found in most theological treatises on the Christian's hereafter. Based on the unsafe assumption that the "destructive fire of science" has annihilated revealed religion, it offers the alternative of the old world ethical system which is not founded on revelation at all—"the system of ontology founded on reason rather than belief"—which advocates the culture of the highest faculties of the mind; and teaches man that, avoiding all vain speculations about God and the soul, or his future self-conscious identity, he should concentrate his attention on existence as he finds it, and learn that all evil springs, not from the life without, but from the heart within, its cravings and its desires. "The attainment of true and lasting happiness is for him alone who from his own being shall eradicate the Cause of Sorrow, shall free his heart from all this grasping at straws in life's fierce waters, and from all this thirst after its false salt waves. And the way in which this may be done . . . is Truth the Fourth," &c.

The writer of the essay would do well to avoid overstating his case. It is not the fact that Buddhism has done more towards civilising the world than any other religion, nor can the proposition be unconditionally accepted that it has added more towards increasing the great sum of human happiness and peace than any other; for it is an indisputable fact that in this imperfect world (so slowly developing towards more perfect ends through the agency, not of one, but of all reasonable religions) war has, after all, been the great civilising agent, the cleansing and purifying principle which has age after age reconstructed higher forms of civilised existence on the ashes of destroyed communities. And war is wholly and absolutely obnoxious to Buddhist principles. As for the peaceful and happy conditions of such nations of the world as still recognise the gentle rule of the Buddhist priest, we may still be open to serious doubt. The Burmese, truly, are a light-hearted race—but is this due to self-culture, or environment? In Ceylon, alas! virulent family dissensions ending in crime are (or were but a few years ago) peculiarly frequent.

It is, however, impossible to do more than note the general character of the review. It is well written (there are two delightfully descriptive articles on "The Woman of Burma" and the "Shadow of the Shwe Dagon"), well printed, and well illustrated, and will do much to familiarise the European reader with the active principles of an eastern faith which is older than Christianity, and is professed by 500 millions of his human contemporaries. In the modern world of free thought and toleration such a magazine as this should be welcome, and it would not be surprising if it attained a wide circulation.

[1] *Buddhism*, an Illustrated Quarterly Review. (Printed and published for the International Buddhist Society by the Hantnawaddy Printing Works, Rangoon, Burma.)

TECHNICAL EDUCATION IN GERMANY.

THE excellence of the German system of higher scientific and technical education has been referred to in many articles which have already appeared in NATURE, and the lavish endowment by the State in Germany of the institutions in which the education is given was dealt with in our issue for March 12 (vol. lxvii. p. 433). We are glad to find that public attention is being again directed to the same subject by the *Times*, and that an exhaustive comparison

between the supply of technical education in this country and in Germany was made in a valuable article which appeared in the issue of that journal of November 9.

Most of the English technical schools have, says the writer in the *Times*, for their principal object the teaching of actual industries. In Germany, on the other hand, the term has come to be associated more and more with pure knowledge, and is now commonly reserved for those advanced academies which teach the science underlying industries, but not the industries themselves. What we generally call technical schools are in Germany called "Fachschulen," or Gewerbeschulen, that is, "trade schools," which fall into two main groups. The first group provides instruction for apprentices in the hand trades and for artisans, and may be called "lower trade schools." The second group is large and of great direct importance to the manufacturing industries. The "technical schools" in our large manufacturing towns correspond most nearly to these institutions, which may be called "higher trade schools." Then above these is the highest class, namely, the "technical high schools," which do not correspond to any of our educational institutions. This classification gives a clear view of the special educational provision for industrial life in three broad divisions:—(1) ordinary workmen; (2) those above the grade of workmen from foremen to manufacturers; (3) the high scientific experts, consultants, and innovators.

The main differences between the higher trade schools and the corresponding English technical schools are two—they are more specialised, and are chiefly intended for and used by superior students. There is some provision for workmen, but, as a rule, comparatively little advantage is taken of it. The classes proper are held in the day, and cannot be attended by men at work; those thronged evening lecture-rooms and laboratories filled with young fellows out of the factories and workshops which may be seen in any large manufacturing town in England are almost unknown in Germany. The real meaning of this is that the English schools cater for students in a lower rank of life and teach a much larger number of subjects. The German schools of this class, on the contrary, are quite clearly differentiated. They are not quite so restricted as the description applied to them suggests. The "weaving" schools, for instance, generally embrace all the main textile processes. But they are strictly devoted to some special branch of industry, and their main function is to enable students, who are to occupy superior positions, to acquire a thorough mastery of the skilled processes. Our own textile schools do excellent work, and, so far as affording opportunities to the working classes is concerned, they do far more than the German ones, but they do not command the same superior material. The reason for this is that there is not yet the same inducement to young men who have had a superior liberal education to take up the career of manufacturers' expert. This fact is really at the bottom of the question of scientific education. Given the demand, the supply will follow. The lesson to be learnt from Germany is to make industrial science a sufficiently attractive career for those who have received a superior general education, and particularly a full classical one. The Germans have no belief in the American plan of teaching trades wholly in schools. With regard to finances, these schools are supported by fees, endowments, municipal and State grants, but the general tendency is towards more and more State support and State control.

The technical high schools, of which there are nine, with two more in preparation, represent a further step. As the superior grade of trade schools has been developed from a lower, so the high schools have been developed from trade schools to meet still higher requirements. They have the *status* of universities, are self-governing, and do for the industrial professions what the universities do for the learned professions—that is, impart the highest training in those principles which form the theoretical groundwork of practice. The technical high schools do not supersede or overlap the universities: they supplement them.

The technical high schools have no uniform curriculum, but all of them teach architecture, civil and mechanical engineering, chemistry, mathematics, and physical science. Exceptional subjects are naval architecture (Berlin), mining (Aachen), forestry (Stuttgart), agriculture (Munich). Pharmacy is taught at Brunswick, Karlsruhe, and Stuttgart, and at the last there is a railway, post, and telegraph course. Previous practical knowledge is generally required, as in the trade schools, and more rigidly insisted on. The high school is even less than the trade school a substitute for apprenticeship.

The two really important departments of the technical high schools are chemistry and electrical engineering. It is impossible to exaggerate the importance of the first; it enters into every branch of manufacture, and becomes more potent every day. At the high school teaching and experiment are pushed to the furthest theoretical limits, and the value to Germany is incalculable. Her chemical industries are reckoned to bring in fifty millions a year, but the application of chemical knowledge goes far beyond that and extends into a thousand channels. Nor can any man tell what it may bring forth to-morrow. This is the great lesson in industrial science that the high school has to teach. But it must not be forgotten that chemistry can be, and is, equally well taught at the universities. So, too, electrical engineering, which has also been of immense value to Germany; but her rapid industrial advance in that line, compared with ourselves, is due less to superior knowledge than to the gratuitous retardation of the home industry by Government regulations.

SOCIETIES AND ACADEMIES.

London.

Physical Society, December 11.—Mr. James Swinburne, vice-president, in the chair.—A method of mechanically reinforcing sounds, by the Rev. T. C. **Porter**. If a tuning-fork be sounded and placed in a flame, there is a very marked reinforcement of the sound. This is proved not to be due to resonance in the ordinary sense, but to the change from continuous to intermittent combustion. In certain circumstances the impulses given to the air external to the flame, by the waves of burning gas, are more forcible than those given by the unaided sounding body. Thus a new way of reinforcing the sounds given by a vibrating body is found, and the rest of the paper demonstrates this for the phonograph, a *flame* being used instead of the ordinary *trumpet*. Coal-gas and air are brought by tubes into the chamber of the "reproducer" and thence to a jet, where they are burnt. The vibrations of the reproducer are thus impressed on the issuing gas and air, which burn synchronously with them, the sounds thus emitted being easily heard over a large room. In practice it is found best to spread out the flame by a second jet of air, or of mixed air and gas, placed close to the first jet and at right angles to it. The author describes the nature and quality of the sounds emitted by the flame, and the modifications of these which may be produced.—The Simmance-Abady "flicker" photometer, by Messrs. **Simmance** and **Abady**. The principle of the flicker photometer, discovered by Prof. O. N. Rood ten years ago, has frequently been remarked on, but attempts to design a trustworthy apparatus depending upon this principle have hitherto been unsuccessful. The authors, guided by the following rules, have designed a photometer which is capable of balancing and comparing the most violently contrasted tints:—The light-effects must be in juxtaposition without any apparent division line, and must move, oscillate, or rotate so that the point of juncture of the rays of the two lights passes and returns entirely across the vision field. Any hiatus, or longer exhibition of one light than the other, biases the result. The observation surfaces, or surfaces upon which the light rays fall, must be at exactly the same distance from the eye, at exactly the same angle in relation to the line of sight, and must be of pure white, such as is afforded, for example, by a clean chalk, plaster of Paris, magnesium carbonate, or barium sulphate; any tint affects the accuracy of the result. The observation surfaces must also themselves in turn occupy the field of vision; an apparent movement or optical illusion does not afford accurate results.—Mr. Rollo **Appleyard** exhibited a "conductometer" the theory and mechanical details of which are fully described in the *Proceedings* of the Institution of Civil Engineers, vol. cliv., session 1902–3, part iv.—Prof. L. R. **Wilberforce** exhibited

a model to illustrate various properties of wave-motion. The model consists of a series of brass balls suspended in a line by spiral springs and capable of transverse or up and down motion. The balls can be set in vibration by releasing them from extreme positions by means of triggers, one set of triggers controlling the up and down motion, and another set the pendular.

Chemical Society, December 3.—Prof. W. A. Tilden, F.R.S., president, in the chair.—The molecular formulæ of some fused salts as determined by their molecular surface energy, by Mr. J. F. **Bottomley**. Measurements of the variation of capillary rise of fused sodium and potassium nitrates with temperature have shown that these salts probably exist in a fused state in the form of complex molecules containing nine or ten of the molecules represented by the simple formulæ $NaNO_3$ and KNO_3.—The atmospheric corrosion of zinc, by Mr. G. T. **Moody**. It is shown that the semi-crystalline scale formed on the surface of the metal when zinc is exposed to the atmosphere consists of a hydrated carbonate. The same compound is formed when zinc is dissolved in a solution of carbon dioxide and the resulting solution is exposed to the air. From these experiments the author concludes that carbon dioxide is the principal agent in the atmospheric corrosion of zinc, as he has already shown it to be in the case of iron.—The formation of urea by the direct hydrolysis of lead cyanate, by Mr. A. C. **Cumming**. When lead cyanate is boiled with water it is decomposed with the formation of urea and lead carbonate.—Acid salts of monobasic acids, by Mr. R. C. **Farmer**. An account of the physical properties of some acid salts of benzoic acid and their derivatives is given.—The solubility curves of the hydrates of nickel sulphate, by Messrs. B. D. **Steele** and F. M. G. **Johnson**. Solubility curves are given for the heptahydrate, α- and β-hexahydrates, and for the dihydrate.—Action of malt diastase on potato starch paste, by Messrs. B. F. **Davis** and A. R. **Ling**. When malt diastase is heated in aqueous solution at temperatures in the neighbourhood of 60° C. its action upon starch paste is weakened, and *dextro*glucose appears among the products of hydrolysis.—The formation of phloroglucinol by the interaction of ethyl malonate with its sodium derivative, by Mr. C. W. **Moore**. It is shown that the condensation product formed in this reaction is ethyl phloroglucinoldicarboxylate, and not the tricarboxylate as stated by von Baeyer.

Mathematical Society, December 10.—Prof. H. Lamb, president, in the chair.—The following papers were communicated:—Mr. R. J. **Dallas**, Proof of a formula in elliptic functions.—Dr. E. W. **Hobson**, On modes of convergence of an infinite series of functions of a real variable. The condition of uniformity of convergence is known to be sufficient to secure the continuity of the function expressed by the sum of an infinite series the terms of which are continuous functions, but the function may be continuous without the convergence being uniform. The necessary and sufficient conditions have recently been made out, and new proofs of them are given in the paper. Another matter discussed is the nature of the conditions which are necessary and sufficient to secure that, when the terms of the series are integrable without being continuous, the function expressed by the sum of the series is integrable. The methods of proof depend upon applications of the Heine-Borel theorem in the theory of aggregates.—Mr. W. H. **Young**, On the distribution of the points of uniform convergence of a series of functions. It is proved that the points in question form an "inner limiting set," and that, conversely, given any such set of points, a series of functions can be constructed having these points, and these points only, as points of uniform convergence.—Rev. F. H. **Jackson**, A generalisation of Neumann's expansion of an arbitrary function in a series of Bessel's functions.—Prof. A. C. **Dixon**, On many-valued Newtonian potentials. The paper deals with a theory on the lines of Riemann's theory of the Abelian functions, but relating to space of three dimensions. The various values of the potential function become different one-valued functions in a bounded simply-connected region, and these various values must be supposed to exist in different co-extensive examples of this region. The chief question is that of the existence of a potential one-valued throughout all the coextensive examples of the region, and having a simple pole at an assigned point in a particular example. Two values of a many-valued potential, which are permuted by description of an irreducible circuit, may differ by a constant or by a variable function.—Mr. P. E. B. **Jourdain**, On functions all of whose singularities are non-essential.—Prof. J. D. **Everett**, On normal and anti-normal piling. The object of the paper is to exemplify a convenient method of dealing with systematic assemblages of points. Normal piling denotes a particular homogeneous assemblage, whereas the arrangement in anti-normal piling is made up of two homogeneous assemblages. Both arrangements give the maximum of compactness.—Lieut.-Colonel Allan **Cunningham** made a preliminary communication on some properties of Fermat's numbers. If $F_n = 2^{2^n} + 1$ and P is a product of F's, the smallest suffix (a) exceeding unity and the highest not exceeding $2^a - 1$, then $2^{P-1} \equiv 1 \pmod{P}$ and $2^{P(P-1)} \equiv 1 \pmod{P^2}$.

Entomological Society, November 18.—Prof. E. B. Poulton, F.R.S., president, in the chair.—Mr. G. C. **Champion** exhibited numerous specimens of both sexes of *Xyleborus dispar*, from Moncayo, Spain, taken out of beech-stumps.—Mr. F. B. **Jennings** exhibited (1) on behalf of Mr. H. Britten, of Great Salkeld, Cumberland, a specimen of *Tropiphorus tomentosus*, Marsh., from Great Salkeld, showing the deciduous false mandibles intact; (2) a ♀ specimen of *Anchomenus parumpunctatus*, F., from the same locality, showing a malformation of the middle right tibia which was abnormally thin, and bent in the centre, but thickened at the base; the right antenna also had the last seven joints flattened and dilated. Mr. Jennings also exhibited, on his own behalf, *Apion sanguineum*, De G., taken at Brandon, Suffolk, in August last, on Rumex.—Mr. H. St. J. K. **Donisthorpe** exhibited *Apium sorbi*, ♂, taken this year at Freshwater, Isle of Wight, and said that the ♂ of this species was extremely rare.—Mr. M. **Burr** exhibited two ♀s and two ♂s of the largest known earwig, *Anisolobis colossea*, Dohrn., from New South Wales, representing the extremes of size, the average size being between these two extremes.—Mr. A. J. **Chitty** exhibited a specimen of the beetle *Homalium testaceum*, taken in Blean Wood in 1900, and a pair of bees, *Nomada guttulata*, of which the ♂ has never been recorded hitherto in Britain, taken by him at Huntingford, Kent, in May last.—Dr. Norman **Joy** exhibited (1) *Euconnus mäklini*, Mannerh., taken at Bradfield in July, 1901, new to the British list of Coleoptera; and (2) a series of beetles taken at Bradfield at the exuding sap of trees attacked by *Cossus ligniperda*.—Colonel J. W. **Yerbury** exhibited specimens of rare British Diptera, including *Leptopa filiformis*, Lett., *Thyreophora furcata*, *Pelidnoptera nigripennis*, and *Lucina fasciata*.—Dr. T. A. **Chapman** exhibited specimens of *Chrysophanus phlaeas* captured at Reigate, Locarno, and in Spain, showing the apparent effects of temperature on the coloration and wing markings.—Mr. G. J. **Arrow** showed specimens and diagrams illustrating a remarkable kind of variability noticed in beetles of the Trogid genus Acanthocerus. These beetles have the faculty of rolling themselves into a ball, in the interior of which all the vulnerable parts are enclosed. The head forms a large triangular plate in which the eyes appear half on the upper and half on the lower surface. In some examples of the species exhibited (*Acanthocerus relucens*, Bates) the upper division of the eyes forms a large, nearly circular mass, while in others it is reduced to a mere thin vestige, and in extreme examples of another species of the genus it was found to vanish altogether.—Prof. **Poulton** showed an exhibit sent by Mr. A. H. Thayer, of Monadnock, N.H., U.S.A. The greyish silhouettes of two butterflies were represented in a tint nearly the same as the background, but sufficiently distinct to be easily recognisable. On one side of one silhouette a row of white spots had been placed in a submarginal position. It was evident that the adjacent border was thereby rendered far less distinct than that of the opposite side of the silhouette, or of both sides of the other silhouette. The spots in position and shape were approximately as in *Papilio asterias*, and Mr. Thayer considered they possessed a similar significance in this butterfly. Prof. Poulton also exhibited specimens of *Drurya antimachus*, together with the butterflies which he suggested as forming a group synaposematic with it. The central species

appeared to be *Acraea egina*, round which clustered a number of other species of the same genus, so much alike as to be probably indistinguishable upon the wing. Examples of these were exhibited, viz. *A. zetis*, *perenna*, *rogersi*, and *pharsalus*. Another beautiful papilionian member of the group, *P. ridleyanus*, was also shown. The pattern was nearest to that of the male *A. egina*. In fact, so close was the resemblance that Godart had been entirely misled by it, and had described the Papilio under the name of *zidora* as the female of *Acraea egina*.—Mr. Edward **Saunders**, F.R.S., communicated a supplementary note to a paper entitled "Hymenoptera Aculeata Collected by the Rev. A. E. Eaton, in Madeira and Tenerife, in the Spring of 1902."

Geological Society, November 18.—Sir Archibald Geikie, F.R.S., vice-president, in the chair.—Notes on some Upper Jurassic Ammonites, with special reference to specimens in the University Museum, Oxford, by Miss Maud **Healey**. In rearranging the Upper Jurassic fossils in this museum the prevailing misconception with regard to Sowerby's species *Ammonites plicatilis* and *Am. biplex* came under notice. The type-specimen of *Perisphinctes plicatilis* (Sow.) is refigured and described. It appears to be an Upper Corallian form, and is usually taken as the zone-fossil of that horizon. Sowerby's two figures of *Perisphinctes biplex* represent different specimens. One, probably from a Kimmeridge Clay nodule found in the Suffolk Drift, is refigured and described. It would be wisest, the paper suggests, to abandon the name, or at least to restrict it to the abnormal specimen to which it was attached. The original specimen of *Perisphinctes variocostatus* (Buckland) came from the so-called Oxford Clay at Hawnes, but evidence that it was really derived from the Ampthill Clay was given. Sowerby's *Ammonites rotundus* is doubtfully identified as a variety of *Olcostephanus Pallasianus* (d'Orb.). It was derived from the Kimmeridge Clay of Chippinghurst, and is the zone-fossil of the Upper Kimmeridge Clay. —On the occurrence of Edestus in the Coal-measures of Britain, by Mr. E. T. **Newton**, F.R.S. This genus was originally described from the United States, and was afterwards recognised in Russia and Australia. The genus was placed with Helicoprion and Campyloprion in the family Edestidæ. The specimen here described was obtained by Mr. J. Pringle from one of the marine bands between the "Twist Coal" and the "Gin-Mine Coal," in the Smallthorn sinking at Nettlebank (north Staffordshire). The specimen is a single segment of a fossil closely resembling *Edestus minor*, and consists of an elongated basal portion, bearing at one extremity a smoothed, enamelled, and serrated crown. The fossil is not to be referred to any existing species, and a new name is given to it. While it seems most in accordance with present knowledge to regard the "spiral saw" of Helicoprion as the symphysial dentition of an Elasmobranch, possibly allied to the Cestracionts, it does not seem so probable that the forms referred to Edestus are of the same nature. The author thinks the latter are more likely to be dorsal defences.

Zoological Society, November 17.—H.G. the Duke of Bedford, K.G., president, in the chair.—Mr. Henry **Scherren** exhibited and made some remarks on the largest horn of *Rhinoceros simus* yet obtained from the Soudan. He directed attention to the fact that the species appeared to be fairly numerous on the northern boundary of the Congo Free State and in the adjacent parts of the Soudan. —Mr. R. I. **Pocock** exhibited a piece of basalt, picked up on the coast of Victoria, Australia, which contained a web of the marine spider *Desis kenyonae*. This served to illustrate the habit of the spiders of the genus Desis of spinning a closely woven sheet of silk over a crevice in the rock as a protection against the rising tide.—Mr. Pocock also gave an exposition, illustrated by drawings, of a new suggestion as to the use of the white rump-patches of Ungulata, with special reference to the races of Burchell's zebra.—Mr. E. E. **Austen** exhibited and made remarks on specimens of *Glossina palpalis*, the species of tsetse-fly which is concerned in the transmission of "sleeping sickness" in the Uganda Protectorate. He also exhibited, for the sake of comparison, specimens of four other species of tsetse-flies, including *Glossina longipennis*, which occurs in Somaliland, and may possibly prove destructive to the transport animals of the Somaliland Field Force.—Mr. Oldfield Thomas, F.R.S., exhibited, on behalf of Mr. W. E. **de Winton**, a drawing of a skin of a female gazelle—probably *Gazella muscatensis* —from Sheik Oman, near Aden, which showed a perfect hair-whorl on the withers. This whorl had been found to be absent in the male.—Mr. C. Tate **Regan** read a paper entitled "A Revision of the Fishes of the Family Loricariidæ," in which nearly 200 species were recognised as valid, 35 being described as new to science.—Dr. Blanford read, on behalf of Mr. V. V. **Ramanan**, a communication entitled "Early Sanskrit References to the Tiger," in which it was pointed out that the tiger was frequently alluded to in Sanskrit literature, and that Colonel Stewart was in error in stating at a previous meeting that there was no Sanskrit name for this animal.—Mr. F. E. **Beddard**, F.R.S., read a paper on the trachea and lungs and other points in the anatomy of the hamadryad snake (*Ophiophagus bungarus*).—Mr. G. A. **Boulenger**, F.R.S., read a report on the fishes collected by Mr. Oscar Neumann and Baron Carlo von Erlanger in Gallaland and southern Ethiopia. Examples of 19 species, 4 of which were new, were contained in the collection, and these were enumerated and described.

Royal Meteorological Society, November 18.—Captain D. Wilson-Barker, president, in the chair.—Dr. H. R. **Mill** and Mr. R. G. K. **Lempfert** gave an elaborate and interesting paper on the great dustfall of February and its origin. From the maps exhibited it appears plain that the dust reported on February 21 or 22 fell over nearly all parts of England and Wales to the south of a line drawn from Anglesey to Ipswich, except in parts of north Cornwall, Somerset, Wilts, and mid-Wales. The dust usually attracted attention either in the form of a dense yellow haze, like a London fog, or as a reddish-yellow powder, lying thickly on trees and roofs. The fall was often accompanied by temperatures considerably above the average, and by remarkably low relative humidities. In order to ascertain whether the composition of the dust threw any light on its origin, about fifty samples were submitted to the Geological Survey and examined by Dr. J. S. Flett. In addition to the coarser particles, all the samples contained a very fine-grained reddish clay, the particles of which were too minute to be determined mineralogically. This clay was certainly derived from some source beyond the British Isles, but it was not distinctive enough to afford much evidence as to its place of origin. Maps have been constructed showing the distribution of the dust and the meteorological conditions prevailing over the period when it appeared. These form the basis of a discussion by Mr. Lempfert as to the place of origin and the direction of travel of the air which was passing over western Europe at the time in question. The trajectories of the air which reached the southern half of England can be traced backwards in a south-westerly direction to the neighbourhood of the Azores, but here it turns to the south, and finally to the south-east, and is carried back to the north-west coast of Africa on the morning of February 19. The authors are therefore of opinion that there is reason to believe that the air which reached the southern half of England on February 22 started from the north-west coast of Africa on February 19, and they consider this affords strong evidence of the African origin of the dust, and of its having travelled to north-west Europe by a path not very different from that indicated by the trajectories.

Linnean Society, December 3.—Prof. J. Bretland Farmer, F.R.S., vice-president, in the chair.—Dr. Eric **Drabble** gave an account of his recent researches on the anatomy of the roots of palms, illustrated by lantern-slides from his drawings. He stated that the roots of more than sixty species have been examined. Essentially similar results have been obtained from each. It appears that the "medulla" in palm-roots is merely that portion of the common ground-parenchyma, arising at the non-stratified apex, which becomes enclosed distally by fusion of the procambial strands, and hence differs in no respect from the external "cortical" parenchyma. An attempt was made to extend this idea to other vascular plants, and the suggestion was put forward that all ideas of "monostely" and "polystely," and of "medulla" and "cortex" as

separate morphological entities, are based on an artificial conception of the structures involved.—In a paper by Dr. Arthur **Willey,** F.R.S., an account was given of twenty-eight species of littoral Polychæte worms from South Africa, of which four are new. The specimens had been carefully prepared, and the author is satisfied with the results. He comes to the general conclusion that the annelid fauna of the Indo-Pacific region may be said to be composed of an assemblage of endemic, Caribbean, and Mediterranean constituents.—Notes on *Myriactis Areschougii* and *Coilodesme californica,* by Miss May **Rathbone.** The species of Myriactis in question is parasitic on *Himanthalia lorea,* forming very small tufts with a cushion of large torulose colourless cells, deeply sunk in the thallus of the host. Material was obtained from Cumbrae in March which shows penetrating rhizoids belonging to some parasitic alga; they start from the base of the cushion and travel far in the tissues of the host, and the conclusions of the author are that these rhizoids act as stolons for propagating the plant, which seems rather to be an endophyte than a parasite.

Anthropological Institute, December 8.—Mr. H. Balfour, president, in the chair.—The Rev. R. A. **Bullen** exhibited a series of polished and other slate implements from Harlyn Bay, Cornwall. The implements were found on the site of a late Celtic cemetery, the graves of which are lined with slate, buried some twelve feet beneath blown sand. Mr. Bullen was of opinion that the implements showed unmistakably the hand of man, but, in the discussion which followed, Mr. C. H. Read expressed his firm conviction that the implements had been worn, not by man, but by the sand which for centuries had been drifting continually over them. Most of the implements, he considered, were simply chippings from the slate linings of the graves, worn by the sand to their present shape.—Dr. William **Wright** read a paper on skulls from round barrows in east Yorkshire, the skulls in question being now in the Mortimer Museum at Driffield. About eighty of them were examined. The interments, from the evidence of the finds, appeared to date from the early Iron or late Stone age. As to the skulls themselves, Dr. Wright showed that almost every variety of cranial shape was found among them, such widely different types as Sergi's *Ellipsoides Pelasgicus Longissimus, Sphenoides Latus,* and *Cuboides Procerus* being present, while the cephalic index ranged from 69 to 92. In fact, so varied were the types that Dr. Wright felt that it was doubtful whether, in a community of the present day, it would be possible to find a more mixed series of skulls A most interesting point was the extraordinary resemblance, in many cases, between the skulls from any one barrow, in fact it was so striking that Dr. Wright felt inclined to attribute it to the barrows having been family burial-grounds. The resemblance was particularly noticeable in nine skulls taken from one barrow. Four of these had the metopic suture unclosed, and it was interesting, and somewhat unexpected, to find that metopism occurred in long rather than in broad skulls. The conclusion drawn from Dr. Wright's paper was that Thurnam's dictum of "round barrow round skull" was not even approximately accurate so far as skulls from the round barrows in Yorkshire were concerned.

Manchester

Literary and Philosophical Society, November 17.—Prof. H. B. Dixon in the chair.—Prof. **Lamb** exhibited and described two photographs, taken at the Isle of Man by Mr. Hiller, one of which showed very clearly the interference between the direct and reflected waves on the sea coast. The points of intersection of the two systems of waves were particularly well marked. Mr. T. **Thorp** exhibited a small glass tube containing a little radium bromide at the sealed end, and terminating in a bulb at the other end. The whole formed a vacuum tube, and was a very convenient and portable instrument for showing the fluorescence of radium bromide on a barium platino-cyanide screen in the dark. He also stated that the bulb caused a charged electroscope to discharge very rapidly.—Messrs. R. S. **Hutton** and J. E. **Petavel** described some experimental work which they have undertaken with the view of studying the effect of high gaseous pressures upon electric furnace reactions. The investigation is being carried out in the electrochemical laboratory of the Manchester University. The preliminary results only were given, progress having been necessarily slow up to the present. The several dispositions of the furnace and of the arcs were described, and photographs of them thrown upon the screen. To obtain satisfactory results it is necessary to exceed the laboratory scale of operations. For the present the work has been confined to the production of calcium carbide, aluminium and nitric acid as effected by pressures up to 150 atmospheres.

Dublin.

Royal Dublin Society, November 17.—Prof. W. F. Barrett, F.R.S., in the chair.—Sir Howard **Grubb,** F.R.S., read the following papers:—(1) The adaptation of the flotation principle to large telescope mountings; a possible solution of the difficulties encountered in mounting great equatorial instruments; (2) the registration of star-transits by photography; (3) a new form of dipleidoscope; (4) a new surveying instrument for the rapid measurement of horizontal and vertical angles; (5) a new form of position-finder for adaptation to ships' compasses.—Dr. G. H. **Pethybridge** exhibited and described an improved form of potometer.—Sir Howard Grubb exhibited some new forms of geodetical instruments as already described in the *Transactions* of the Royal Dublin Society in May, 1902.

Paris.

Academy of Sciences, December 7.—M. Albert Gaudry in the chair.—Some observations relating to the action of hydrocarbon vapours on animal microbes and on insects, and on the antiseptic *rôle* of oxidising-oxidisable agents, by M. **Berthelot.** In an experiment described by the author, the antiseptic properties usually ascribed to naphthalene were found to be non-existent. There would appear to be a relation between the oxidising power of a body and its antiseptic power.—On the electromotive forces resulting from the contact and the reciprocal action of liquids, by M. **Berthelot.**—On a new Protozoa, *Piroplasma Donovani,* the parasite of an Indian fever, by MM. A. **Laveran** and F. **Mesnil.** A description of a parasite isolated from a case of fever arising at Dum-Dum, near Calcutta. There appears to be no essential difference between this parasite and the Piroplasma already known, in particular, the type *P. bigeminum.* This genus of parasites occupies an important place in veterinary pathology, but this is the first time that a human disease has been traced to it.—On the property of emitting the *n*-rays conferred by compression on certain bodies, and on the spontaneous emission of the *n*-rays by tempered steel, tempered glass, and other bodies in a state of constrained molecular equilibrium, by M. R. **Blondlot.** Numerous substances have been found to give off *n*-rays during compression, recognisable by their action on feebly illuminated phosphorescent calcium sulphide. Substances such as tempered steel and glass, permanently under strain, appear to give off these rays indefinitely.—Observations on the Leonids and Bielids made at Athens during 1903, by M. D. **Eginitis.**—On a theorem on measurable ensembles, by M. Emile **Borel.**—Generalisation of a theorem of Laguerre, by M. A. **Auric.**—On the quality of helices used in aërostats, by M. Charles **Renard.**—On the intensity of the light produced by the sun, by M. Charles **Fabry.** The conclusion is drawn from the experiments described that the illuminating power of the sun at the zenith, at its mean distance, is, at the level of the sea, 100,000 candles.—On the direction of permanent magnetisation in certain volcanic rocks, by MM. Bernard **Brunhes** and Pierre **David.**—The effect of time in the comparison of the luminous intensity of coloured lights, by MM. André **Broca** and D. **Sulzer.** If two lights of different colours are compared in a photometer, the equality is affected by the time during which the disc is exposed to the light. The effects are due to differences in the retinal fatigue for the different colours.—On a new mode of calculating the heats of combustion of organic compounds, and on some of its consequences, by M. P. **Lemoult.**—Researches on azo-compounds. A new mode of formation of the indazylic derivatives, by M. P. **Freundler.**—The action of hydro-

cyanic acid upon aldehyde-ammonia and analogous compounds, by M. Marcel **Delépine.** The results of the experiments described show that the ordinary equations for expressing this reaction require some modification.—A new reaction of hydroxylamine, by M. L. J. **Simon.**—A new method for the preparation of aldehydes, by M. L. **Bouveault.** Disubstituted formaldehydes of the type H.CO.NR.R′ react with magnesium alkyl derivatives to form compounds which, on subsequent treatment with water and dilute sulphuric acid, yield aldehydes. The yields are good, and the method would appear to be of general application.—On the migration of the phenyl group, by M. Marc **Tiffeneau.**—On the esters of isopyromucic acid, by M. G. **Chavanne.** The methyl and ethyl esters of pyromucic acid cannot be obtained by the usual methods, but can be readily isolated by the use of ethyl and methyl sulphates.—On the hydrates of ethyl alcohol, by MM. E. **Varenne** and L. **Godefroy.** From the determination of the viscosity of alcohol-water mixtures, the existence of five hydrates of the alcohol is inferred.—The production and distribution of some organic substances in *Citrus madurensis*, by MM. Eug. **Charabot** and G. **Laloue.**—On the chemical characters of wine arising from vines which are attacked by mildew, by M. Emile **Manceau.** Such wines are distinguished from ordinary wines by several chemical differences, the most important being the increased proportion of albumenoid matters.—On the determination of the primitive form of crystals, by M. F. **Wallerant.**—The revision of the free marine Nematods of the region of Cette, by M. Etienne **de Rouville.**—A parasitic sporozoa of the mussel and other Lamellibranchs, by M. Louis **Léger.**—On the filosity of potatoes, by M. G. **Delacroix.** A study of the cause of the tendency to develop buds which lengthen considerably and remain thin.—On the Permian system in the French and Spanish Pyrenees, by M. J. **Caralp.**—Observations relating to the Tectonic in the mountain valley of Jalomita, Roumania, by M. J. **Bergeron.**

New South Wales.

Linnean Society, September 30.—Mr. Henry Deane, vice-president, in the chair.—The botany of Norfolk Island, by Mr. J. H. **Maiden.** No new species is described, but 45 Phanerogams (Dicotyledons 24, Monocotyledons 21) and 17 Cryptogams (ferns 6, lichens 10, fungus 1) are recorded for the first time as indigenous to the island. Of the Algæ gathered from the shores, all (with one exception) are new records for this particular locality. The paper contains a careful list of introduced plants. Section ii. of the paper deals with early general accounts of the vegetation, bibliography, Ferdinand Bauer and Norfolk Island, early Government gardens on the island, and Phillip Island. An almost complete collection of the Norfolk Island flora is now in the National Herbarium, Sydney.—The slime of *Dematium pullulans*, De Bary, by Dr. R. Greig **Smith.** A race of *Dematium pullulans* was found with *Bact. acaciae* in the gum-flux of the peach and almond. From cultures upon solid and in fluid media a slime was obtained, which proved to be a pararabin.—The physical geography of the Blue Mountains and the Sydney district, by Mr. E. C. **Andrews.** Repeated elevation of subaërially carved and successively formed plains or almost plains (peneplains) is the key to the history of the Blue Mountain and Sydney areas in late geological time. These plains, developed near sea-level, were successively raised to heights of 700–3000 feet above the same base. The elevations imposed a dome-shaped surface upon the area, the axis of the dome being drawn out in a meridional direction. The growth of the present rivers shows the revival of stream activities after a late Tertiary uplift, when the cycle of erosion immediately preceding the present one had advanced to the stage of completion.

October 28.—Prof. T. W. Edgeworth David, F.R.S., vice-president, in the chair.—The geology of the Glass House Mountains and district, Queensland, by Harald I. **Jensen.**—On a new species of Callitris from New South Wales, by R. T. **Baker.** This pine attains a height of about 20–30 feet, and a diameter of from 1–2 feet. The branchlets are slender, with a drooping habit, giving it a facies different from the other Australian species; the fruit cones are almost identical with those of *C. Muelleri*, whilst the terete branchlets are similar to those of *C. robusta*, R.Br. It appears to be a very local species, for after a botanical survey of the pines of this State it has so far never been found except on the top of the Gowie Ranges, north of Rylstone. The name *C. gracilis* is proposed for it in reference to the slender branchlets.—The effect of the Bassian Isthmus upon the existing marine fauna: a study in ancient geography, by C. **Hedley.** The union of Tasmania and Australia has been exhaustively dealt with by Mr. A. W. Howitt, and Prof. Spencer has shown how Tasmanian animals entered Victoria by this vanished land-bridge. The present memoir discusses the barrier such an isthmus would oppose to migration of the marine fauna.—The gum and byproducts of *Bacterium sacchari*, by Dr. R. Greig **Smith.** The gum has been identified as a galactan. The byproducts in the fermentation of saccharose are carbon dioxide, ethyl alcohol, succinic, lauric, palmitic, acetic and formic acids.

DIARY OF SOCIETIES.

THURSDAY, December 17.

Linnean Society, at 8.—On the Docoglossa; a Study in Evolution: H. J. Fleure.

Institution of Electrical Engineers, at 8.—The City and South London Railway; Working Results of the Three Wire System applied to Traction: P. V. McMahon.

FRIDAY, December 18.

Institution of Mechanical Engineers, at 8.—An Inquiry into the Working of various Water-Softeners: C. E. Stromeyer and W. B. Baron.

Institution of Civil Engineers, at 8.—The Action of the Sea upon the Foreshore: C. B. Case.—The Causes of the Loss of Beaches: F. W. Cable.

SATURDAY, December 19.

Essex Field Club, at 6.30 (Essex Museum of Natural History, Stratford).—Report on Protection of Birds in Essex: F. Dent.—Some Pictures of Bird Life at Home and Abroad: R. B. Lodge.

MONDAY, December 21.

Institute of Actuaries, at 5.—The Income Tax as affecting Life Offices, with Special Reference to some Recent Decisions: J. E. Faulks.

TUESDAY, December 22.

Institution of Civil Engineers, at 8.—On the Resistance of Plane Surfaces in a Uniform Current of Air: Dr. T. E. Stanton.

LUNGE'S SULPHURIC ACID.

A Theoretical and Practical Treatise on the Manufacture of Sulphuric Acid and Alkali, with the Collateral Branches. By George Lunge, Ph.D., Professor of Technical Chemistry in the Federal Polytechnic School, Zurich. Third edition, revised and enlarged. Pp. xxvii + 1214. (London: Gurney and Jackson, 1903.) Price 2*l.* 12*s.* 6*d.*

THE volumes before us, although bearing the above comprehensive title, in reality deal only with the manufacture of oil of vitriol, and together constitute vol. i. of the complete work. It is now upwards of a quarter of a century since this work was first published, and, thanks to the assiduity and painstaking zeal of its author, it still remains the standard treatise on the subject. Ten or a dozen years ago, at the time of the appearance, in fact, of the second edition of this work, it might have been supposed that all that need be known or stated with regard to a manufacture so highly specialised as that of oil of vitriol was already known, and was described in Dr. Lunge's classical work. But it is a striking instance of the essentially progressive character of chemical science that, even in a branch of its application so well established as this, in which, under the stress of competition, some of the acutest intellects which have ever devoted themselves to chemical technology have laboured for years with a view to make it perfect, there should have arisen during the last ten or twelve years what is practically a revolution in the manufacture—a new departure, in fact, which bids fair to alter the whole complexion of the industry.

It is this circumstance, no doubt, which has primarily led to the publication of this new edition. During the last few years there has been an enormous development of the manufacture of sulphuric anhydride, and oil of vitriol itself is being made in increasing amounts by contact-processes. It is commonly believed that the chamber process is doomed. Perhaps it is. But threatened industries, like threatened men, occasionally live long. Indeed, it is Dr. Lunge's opinion that the old lead-chamber will in all probability still yield the principal supply of ordinary sulphuric acid for many years to come. It is interesting to see how, indeed, the more modern processes have indirectly afforded a fresh lease of existence to the older one. The lead-chamber with all its appurtenances is too costly a plant to be lightly discarded, and so long as it can be kept going at a profit, so long will it continue to be used. The manufacture of oil of vitriol by the chamber process is one of those highly developed industries in which, by reason of its magnitude, small economies are all important, and, as Dr. Lunge's book shows, it is only by constant vigilance to prevent waste, and by promptitude to make use of improvements, that it can stave off what some people regard as its inevitable doom.

The compiler of a work of this character who seeks to achieve what Dr. Lunge defines to be his purpose—namely, to furnish chemical manufacturers with a trustworthy guide for actual practice as well as exhaustive scientific and technological information for all students of this branch of industry—must be prepared to suffer many rebuffs and disappointments in his search for truth. There is an obvious reference to this fact in the allusion to the studied reticence of the great acid trusts and "the somewhat narrow-minded apprehension" which fears "that by enlightening their neighbours they might injure their own interests." Luckily for the cause of technology there are manufacturers who, in the words of the author, "are far-seeing and large-hearted enough" not to restrict their experience "within the precincts" of their own business circle. To these men—and the list is a goodly one—Dr. Lunge is indebted for much valuable information.

The interested reader will naturally first turn to Dr. Lunge's account of the so-called contact-process, the process which, as already stated, in some form or other probably marks the direction which the manufacturer of the future is destined to take. In this respect the third edition, which, *pace* Dr. Lunge, we hope does not represent the last opportunity the author will have of treating the subject, constitutes a new departure, and is perhaps its most valuable, as it is its most interesting, feature. Thanks to the special communications of nearly all those who have been mainly instrumental in developing it, and more especially of the large firms concerned, Dr. Lunge has been enabled to elucidate, for the first time, the history of this special branch of a great industry. For much of our information concerning its present state, we are indebted to the Badische Anilin- und Soda-fabrik, who permitted Dr. Knietsch to make known many details of the process in the course of his remarkable and interesting lecture to the Berlin Chemical Society two years ago. The account then given has been supplemented by new and valuable information from the same firm, as well as from other manufacturers in Germany.

As has already more than once happened in the history of technology, and especially in chemical technology, the fundamental idea on which the modern method of making concentrated oil of vitriol depends had its origin in this country. It was Davy who, in 1817, first directed attention to the occurrence of what were at one time classed as "catalytic," but are now generally called "contact," reactions—phenomena which immediately engaged the attention of his relative, Edmund Davy, and thereafter of Döbereiner and Berzelius. But what is of special interest is that some years before Berzelius published his well-known paper on catalysis, the attempt was made in this country to turn contact action to account in the manufacture of oil of vitriol. In 1831 a vinegar manufacturer of Bristol named Peregrine Phillips took out a patent for "certain improvements in manufacturing sulphuric acid, commonly called oil of vitriol, viz., firstly, causing an instantaneous union of the sulphurous acid gas with the oxygen of the atmosphere, and so save saltpetre and the cost of vitriol chambers, by drawing them in proper proportions, by an air-pump or otherwise, through an ignited tube or tubes of platina, porcelain, or some material not acted on by heated sulphurous

acid gas, in which are fine platina wire or platina in any finely divided state. The sulphuric acid formed is absorbed in a lead-lined tower, filled with pebbles over which water is made to trickle down."

With reference to this patent Dr. Lunge writes:—

"Undoubtedly we have here the fundamental features of the contact-process as now employed, and Peregrine Phillips must be called its inventor in the same way as Dyar and Hemming are the inventors of the ammonia-soda process. The history of both inventions presents some common features. Made and patented in England, within a very few years of each other, by persons otherwise absolutely unknown, evidently neither trained chemists nor practical manufacturers in their respective lines, they remained almost unnoticed in the country of their birth; they were taken up in foreign countries, at first by men of science, afterwards by manufacturers, but only after having suffered many checks were they brought to full technical success, both abroad and in England, after an almost equally long interval during which all attempts in that direction were judged hopeless."

There is no "tariff-wall" against the importation of English ideas into Germany. "Almost immediately after the publication of Phillips's patent two German scientists repeated his experiments." These were Magnus and Döbereiner, and on their observations Kuhlmann based his patent of 1838. Three years before this time Clement-Desormes was reported to have written, "I am convinced that in at most ten years it will be possible to make sulphuric acid on the large scale from its constituents without lead-chambers, nitric acid or nitrates." Events somewhat belied this confident prediction. What, however, was not possible during the first half of the last century was found to be perfectly practicable during the later years of the second half.

The space at our disposal precludes any attempt to show in detail how this result has been accomplished. All the main facts are set out in Dr. Lunge's account and in the interesting communications from the Badische Anilin- und Soda-fabrik, the Höchst Farbwerke, from the Schroeder-Grillo firm, the Mannheimer Verein, and last, but not least, in the account of the process as gradually developed under the direction of Clemens Winkler at Freiberg. Together the whole story constitutes one of the most interesting chapters in the history of the development of the manufacture of an article the production and consumption of which have been held to be a measure of the degree of a country's civilisation.

RELIGION, LIFE AND GENIUS.

Grundriss der Religionsphilosophie. By D. Dr. A. Dorner. Pp. xviii + 448. (Leipzig: Verlag der Dürr'schen Buchhandlung, 1903.) Price 7 marks.

Gesammelte Aufsätze zur Philosophie und Lebensanschauung. By Rudolf Eucken. Pp. 242. (Leipzig: Verlag der Dürr'schen Buchhandlung, 1903.) Price 4.20 marks.

Friedrich Nietzsche: sein Leben und sein Werk. By Raoul Richter. Pp. vi + 288. (Leipzig: Verlag der Dürr'schen Buchhandlung, 1903.) Price 4 marks.

THE author of the "Grundriss der Religionsphilosophie" brings to his exposition a wide knowledge of the literature of the subject, and a very comprehensive grasp of the forms which religion has assumed in various countries and at different stages of its development. This preliminary mastery of the subject shows itself, not only in the mass of material actually used, but also in the tone of the book; it is marked by a gratifying breadth of treatment. After an introduction on the place of a philosophy of religion in a general scheme of philosophy, there follows a lengthy sketch of the phenomenology of the religious consciousness. From this the author proceeds to the metaphysic of religion, dealing with the existence, essence and actuality of God. This forms the second division of this part; the third is devoted to the psychology of the religious subject, to belief and certainty. The second part is concerned with outward expressions of belief, and deals historically and critically with various developments, from sacrifice to prayer and contemplation, on what may be called the subjective side, and, on the objective side, with local cults, feasts, and symbols. The section concludes with discussions on the relation of religion to morality, knowledge and art. Finally, the laws of the religious life are briefly discussed.

This programme will indicate the comprehensiveness of the author's treatment. The book attains unity in its multiplicity by virtue of the leading idea round which the facts are grouped. Religion, in its widest sense, is taken to be the spiritual life of the individual. As such we expect to find it subject to development; progress is as possible here as elsewhere, and, in fact, the history of the forms of religion shows a gradual purification and emancipation advancing with the gradual refinement of experience. The goal is a union of God and humanity; the end must not be in abstractions, but in the concrete realisation of unity in life and purpose, for which, as for the unity of the world as object of the sciences, the reality of the Divine immanence is the only true ground.

To a great extent this is a position which most thinkers could accept, with the exception of one point. The distinction between the theological and non-theological philosopher rests finally on the view each takes of his ultimate. The author seems well aware that this is the crux; he expressly avoids pantheism, and would assert the rights of the individual. But what, then, is the relation between God and the individual? The answer seems inadequate in so far as certain theological aspects of God are assumed, while no proof is given that contradictions must be unified or that a unity for us can only be grounded in a unity that is for itself. Here the religion and the philosophy make a compromise not altogether unfamiliar. We regret that we cannot follow the author here; others may succeed better, and certainly no one will fail to see that his book is a valuable contribution toward a philosophical treatment of religion.

The essays and addresses of Rudolf Eucken were well worth publishing in book form. They fall into three classes. The first group deals with political philosophy. The author is mainly interested in the opposition of mechanism and spirit which is characteristic of the present age. Man, striving to subdue nature, builds up a vast mechanism; in the human

sphere organisation runs a fervid course; the watchwords are work, efficiency, achievement; the demand is for uniformity; the world is more and more, and yet the individual does not wholly wither; the life of the spirit persists in its claim for recognition, so that there is a progressive differentiation of subject and object, leaving us with the necessity and the problem of a higher synthesis. An essay on the late lamented Finland is characteristic in its generous estimate of the meaning and value of quality as against quantity in political life.

The spirit of this first section pervades the others. The biographical studies, eight in all, range from Aristotle to Karl Steffensen. The study of Goethe is notable for its delineation of a great man, a spirit of informal vigour, broad, active, and penetrating. The discussions on religion resume the thoughts of the first section. As the world grows man seeks escape into the infinite. Religion must progress as the world develops, and so fit itself to effect that redemption of the spirit of man for which the author pleads. The concluding essay deals with the teaching of philosophy, and contains advice worthy of all acceptation.

"Friedrich Nietzsche: sein Leben und sein Werk" is a book that should prove of interest now that Nietzsche's works are being presented in a translation. The life and the work are treated as complementary aspects, a method more than usually fruitful in this case; nothing could be more illuminating for our understanding of this eccentric genius than the Wagner episode; it forms a vigorous chapter in this book, and is a concrete exposition of Nietzsche's character, more effective than any abstract analysis. The second portion of the book, dealing with Nietzsche's writings, is well developed and shows sympathy and insight. To some extent the book is an apology for Nietzsche; the author is clearly aware that not a few will approach the subject with prejudices; not a few will continue to feel that some allowance has to be made for one to whom nature denied a stable equilibrium. As the book says, Nietzsche's power lies in raising rather than solving problems. The author obscures with some partiality those elements in Nietzsche's history which show the natural bias, intending clearly to oppose his own treatment to others which have neglected the genius and made too prominent the pathology of their subject.

G. S. B.

ATOMS AND THE ÆTHER.

Hypothese zur Thermodynamik. Versuch einer leichtfasslichen Darstellung einiger Prinzipe der Molekulartheorie mit Zugrundelegung der Keplerschen Gesetze für die Planetenbewegung. By Victor Grünberg. Pp. vi+73. (Leipzig: J. A. Barth, 1903.) Price 3 marks.

THIS little book consists of a discussion of the elementary portions of the kinetic theory on somewhat novel lines; the main title is therefore misleading; it is true that the subtitle modifies one's expectations to a certain extent, but even then the contents hardly come up to what one is led to hope for. The hypothesis referred to is the following:—the structure of the ether is granular; the ether particles rotate round their axes and circulate round each other; atoms are condensed ether particles, and the circulation of the latter is therefore to be identified with the rotation of the atoms; these in their turn circulate round each other; this motion constitutes the intramolecular rotation; ultimately the molecules circulate round each other.

Four distinct motions are thus introduced, but later on (p. 41) an additional fifth motion appears, another intramolecular motion; in what respect this motion differs from the circulation of the atoms remains a mystery. The molecules (and atoms) attract each other owing to their rotations and to the streams of ether particles which are thereby set up. The centrifugal force arises from the ether pressure when the molecule is made to move in a curvilinear path; this pressure makes equilibrium with the external pressure and the molecular attractions; it is calculated by dividing the centrifugal force by the area of the sphere swept out by the molecule. When this pressure is multiplied by the volume of the sphere, the product is found to be two-thirds of the kinetic energy of the motion of circulation, and this law, which is identified with Krönig's law, is soon extended to the whole gas; incidentally we notice that the volume of N molecules is found to be N^3 times the volume of one (?). It is somewhat unpleasant to be reminded of the fact that the curvilinear motion, with its concomitant centrifugal force, does not exist in the gaseous state, the only state in which Boyle's law holds, and is confined to a state intermediate between gas and liquid, whatever that may be.

In the discussion of the adiabatic formula we obtain a momentary glimpse of Kepler's laws, which are so prominent in the title. When the gas is compressed, say to one-eighth of its volume, the distances of the circulating molecules are halved and their velocities thereby doubled: the temperature being proportional to the kinetic energy becomes increased to four times its value; substituting these results in the adiabatic formula we find for the ratio of the specific heats the value 5/3, as required by monatomic gases. We are afraid that a partial success of this kind may have induced the author to attach more value to his theory than we think it deserves.

Temperature depends originally on the rotation of the ether particles; when heat is supplied to the body its ether particles begin to rotate faster; in consequence of this (why?) their circulation, *i.e.* the rotation of the atoms, slows down; on the other hand, the intramolecular motion of the atoms increases, the rotation of the molecules, and thus their mutual attraction, diminishes, and finally the molecular circulation, on which the molecular pressure depends, increases. Obviously the situation is saved by assuming an odd number of motions which increase and diminish alternately! Can anything more arbitrary or unconvincing be imagined? If the reader thinks that this short review cannot be doing the pamphlet justice, let him try for himself.

J. P. K.

OUR BOOK SHELF.

Animals of No Importance. By D. Dewar. Pp. 113. (Calcutta and Simla: Thacker, Spink and Co.; London: W. Thacker, 1903.)

THE essays collected in this little volume have, with one exception (which made its appearance in the *Indian Daily Telegraph*), been previously before the public in the columns of the *Times of India*. Although his style is occasionally somewhat slangy, the author discourses in a pleasant and readable manner on the habits and mode of life of various living creatures commonly met with by the resident in India, inclusive of some of those to be seen on the voyage. Excluding all such animals as come under the denomination of game—whether great or small—he confines his attention to the less attractive, although in many cases by no means the less obtrusive, members of the animal world, and from this lowly aspect of his subject he has chosen the title of the volume.

As a rule, each of the various essays is devoted in the main to a particular species. One of the most amusing of the series treats of the Indian crow—the miscalled *Corvus splendens*—a bird which, despite its store of mischief, Mr. Dewar allows the possession of some redeeming traits. He can, however, scarcely find words to express his detestation of that noisome pest, the common fly—a detestation shared by all who have resided in the east. On the other hand, the spider is a creature for which the author expresses the greatest admiration, ranking its intellectual powers higher than those of ant, bee, or wasp.

Under the title of the "Malaria Middleman" will be found a good popular account of the manner in which the Anopheles mosquito conveys the malaria germ; although it would have been better had the use of "scientist" been avoided. To one sentence in another article, namely, that "dinosaurs and sea-serpents disported themselves in the ocean" (p. 62), we venture to take strong exception. Although, perhaps, one relating to the movements of the fins of flying-fishes is the only zoological observation of any importance, we may commend the work as an excellent practical example of "nature-teaching," and at the same time as showing how the enforced tedium and confinement of Indian hot-weather life may be mitigated by the intelligent observation of the ways of the uninvited denizens of the bungalow and its immediate surroundings. R. L.

Farming. By W. M. Tod, M.A. With illustrations by Lucy Kemp-Welch. Haddon Hall Library. Pp. vi+268. (London: J. M. Dent and Co., 1903.) Price 7*s.* 6*d.*

THE Haddon Hall Library has hitherto dealt only with various branches of sport; its incursion into the serious domain of agriculture is therefore rather a novelty, but as Mr. Tod indicates in his opening chapter farming is something more than a business. There are probably few men who have not deep in them the desire to cultivate a plot of land or to breed some kind of animal; it is a form of atavism, civilised man gets his amusement from the pursuits out of which he dragged a hard living in the early world, and farming, like shooting and fishing, has long been the rich man's recreation. The professional can still make a living by it, but the amateur often finds his farm little less costly than his shoot. It would be hardly fair to Mr. Tod to say that his book is intended for the latter class of readers; clearly he has in mind the man to whom farming is bread and butter, but he is very sure that if the farmer sometimes finds the butter spread too thin he may look for abundant compensation in the pure joy of life on the land.

Mr. Tod's book then differs from the ordinary textbook of agriculture in treating his subject from a somewhat more generalised and human point of view; he deals with the functions of the soil, the principles of tillage, manuring and cropping, live-stock, and the system on which a farm should be managed, without any elaboration of detail, but with an intelligent appreciation both of the scientific basis of agriculture and of the other considerations which must regulate its practice. Here and there his statements and recommendations are open to criticism; in a country so diversified as Great Britain, the routine of management must change with the shifting conditions of climate and soil, but in the main the book presents a very sound picture of the farming of the midlands and east of England. Mr. Tod's experience is sufficient guarantee that the book is practical; at the same time he is no blind follower of the old paths, but is insistent that agriculture, to be successful, must adapt itself to the altered state of our markets since the great tradition of British farming was established.

The book is clearly and enthusiastically written, and we can cordially recommend it either to the man who has a little place in the country and wants to do something more than blindly follow the lead of his bailiff, or to the general reader interested in the land and desirous of understanding its great industry. To the young landowner or to the boy who is anxious to take up farming as his walk in life the book will give an excellent picture of the work of a well managed farm, and will serve as an inspiriting introduction to a more technical study of the subject. Like all the volumes of the Haddon Hall series, the book is charmingly produced, well printed on good paper, and with some illustrations by Miss Kemp-Welch which catch the true spirit of the English country-side. A. D. H.

Queries in Ethnography. By Albert Galloway Keller, Ph.D. Pp. ix+77. (London: Longmans, Green and Co., 1903.) Price 2*s.* net.

DR. A. G. KELLER'S small book of questions in ethnography is intended for the use of the "intelligent and partially instructed layman." The specialist, he informs us, needs no such manual, and the utterly uninstructed are unfitted to use one with discrimination and result. We agree with him. The 912 questions comprise a very wide range of ethnographical inquiry under the following heads:—(1) maintenance; (2) perpetuation; (3) gratification; (4) religious and superstitious ideas and usages; (5) the societal system; (6) contact and modification.

The system followed has been that developed by Prof. Sumner, of Yale University, and the questions evidently are based also on the admirable "Notes and Queries on Anthropology" edited by Dr. J. G. Garson and Mr. C. H. Read, and on the set of questions issued by Dr. J. G. Frazer. Not one of these books has been written by a field ethnologist, and it is perhaps doubtful whether a field ethnologist would write such a book, as the answers given to such questions by the collector are apt to be snippety, and, with the view of answering the question succinctly, he would be inclined to leave out other descriptive matter which did not appear to be relative to the particular question, but which might be, nevertheless, of supreme importance. Dr. Keller asks "exactly what is meant by 'father,' 'brother,' 'son,' if they do not correspond to our own terms?" This sort of questioning is of little real value; the only satisfactory method is the genealogical one devised by Dr. Rivers (*Journ.* Anthrop. Inst., vol. xxx. p. 74, 1900). Nothing is said about the value of obtaining information concerning different schools of decorative art and the significance of the designs.

Doubtless Dr. Keller's little book will prove of con-

siderable service. Practically all one can say to a traveller is that he should collect full information about everything, and books of this kind are valuable in suggesting topics for inquiry.

Catalogue of the Lepidoptera Phalaenae in the British Museum. Vol. iv. Catalogue of the Noctuidæ in the Collection of the British Museum. By Sir George F. Hampson, Bart. Pp. xx+689, plates lv.–lxxvii., and 125 woodcuts. (London: Printed by Order of the Trustees.) Price 15*s.*; plates 16*s.*

THE previous volumes of this important work appeared in 1898, 1900, and 1901 respectively, and we have now to record the publication of vol. iv., which includes the Agrotinæ, the first of the fifteen subfamilies into which the great family of Noctuidæ is divided; 1139 Agrotinæ are described in the present volume, out of the 10,000 to 12,000 known species of Noctuidæ.

As the Agrotinæ are well represented in Europe and North America, this volume will perhaps appeal to a larger number of lepidopterists than its predecessors, which treated of more showy, but principally tropical, moths. For the plates of Agrotinæ trichromatic photography has been employed, as more suitable to represent the generally dull colours of the Noctuidæ than chromolithography, which is considered better adapted to bright coloured moths, such as Arctiadæ.

Most of the leading lepidopterists of Europe and America have helped to make Sir George Hampson's work more complete by the contribution of specimens, or coloured photographs of unique types, and the loan of co-types.

Descriptions of the known larvæ of Agrotinæ are added from various authentic sources, those of North American species being mostly contributed by Dr. Harrison G. Dyar.

The general arrangement of the book is in all respects similar to that of previous volumes, and the execution of the plates is excellent, though one or two figures may perhaps be somewhat undercoloured—not a very serious point, however.

There are small matters on which we think information, when attainable, might have been added, such as the elevations between which mountain species occur (which is only rarely mentioned) and the latitudes at which Arctic species have been found.

As we may reasonably assume that the increase of our knowledge of moths will be still more rapid in the future than it has been in the past, we can hardly expect Sir George Hampson to complete the Noctuidæ in less than ten or twelve volumes. At a rough estimate it is probable that out of the 1139 species described in vol. iv. less than 300 may have been included in Walker's catalogue of 1856–1866. Rather more than 100 species of Agrotinæ have been described by Sir George himself, either for the first time in the present volume, or in previous publications.

Proceedings of the London Mathematical Society. Vol. xxxv. Pp. 476. (London: Francis Hodgson, 1903.)

A SPECIAL interest attaches to the present volume from the fact that it marks the retirement from the secretaryship of Mr. R. Tucker after thirty-five years of office. Mr. Tucker was elected a member of the Society on October 16, 1865, and two years later he succeeded G. C. de Morgan as secretary. Mr. Tucker has been responsible for the greater part of the editorial duties connected with the issue of the *Proceedings* from part xii. onwards, and he has succeeded in producing a series of English mathematical transactions of which he may well feel proud.

Among the subjects treated in this volume we note Dr. Hobson's presidential address on the infinite and the infinitesimal in mathematical analysis, and papers by Mr. Conway on light propagation in a uniaxial crystal, by Prof. A. C. Dixon on summation of series and expansion of functions, by Prof. Hill on power series, by Prof. Lamb on wave motions, by M. Picard on existence theorems for differential equations (in French), by Mr. Whittaker on harmonic analyses, by Mr. W. H. Young on sets of points and intervals, and many other papers of equal interest.

Insist on Yourself. The only Law of Success. Pp 45. (London: Gay and Bird, n.d.) Price 1*s.* net.

THIS little book is intended to set forth concisely many of Emerson's utterances on the importance and power of individuality. The "thoughts" selected are attractively arranged and nicely printed.

LETTERS TO THE EDITOR.

The Unusual Sky Colours and the Atmospheric Circulation.

PROF. F. A. FOREL writes me concerning my letter in vol. lxviii. p. 623, that although he did not himself observe the coloured ring around the sun prior to the first of last August, yet he has been informed that it was seen in Europe much earlier. The observers and dates quoted by M. Forel, arranged by localities from north to south, are as follows:—Director Rykatcheff, of the Central Physical Observatory at St. Petersburg, noted an opalescent veil surrounding the sun on October 5 and November 9, 1902, January 21, February 10, 18 and 23, March 17, April 5, May 29, and July 26, 1903. Dr. Busch, at Arnsberg, Westphalia, saw the same thing on November 19, 1902, March 21 and 22, 1903, and Prof. Wolf, at Heidelberg, during January, 1903. Dr. Maurer, at Zurich, observed the ring also in January, on March 27 and 28, June 7, 8, 9, and at the end of July, 1903. Therefore, M. Forel says, very properly, that since the phenomenon was observed practically simultaneously in Europe and America, no hypothesis as to why it appeared first in the last named country is needed. While admitting the truth of the statement, I would remark that a faint whitish ring around the sun was recorded by me here as early as June 26, 1902, although it was not noticed again until the close of the year. The equally early appearance over southern England of a large brownish corona, which became smaller but more conspicuous during the summer and autumn of 1902, is described by Mr. T. W. Backhouse in NATURE (vol. lxvii. p. 174).

M. Forel pointed out in the *Comptes rendus* of the French Academy of Sciences for August 10 that in view of the intermittent character of the brilliant colours of the western sky after sunset during the preceding year, produced, he assumed, by the breaking up of the continuous ring of volcanic dust into separate cloud masses which passed successively over Europe, it became of interest to ascertain whether the present Bishop's ring, unlike its predecessor, was always visible in favourable circumstances. The data mentioned, as subsequently sent M. Forel, proved that the new Bishop's ring was visible only at irregular intervals, as he had surmised. Now, if this phenomenon, as well as the discontinuous sunset glows, were caused by the passage of isolated masses of volcanic dust, it seems possible, by comparisons with observations at distant stations, not only to trace the direction of their drift, but also to determine their approximate velocity. Accordingly, the records at Blue Hill of the occurrence of Bishop's ring and of abnormal glows after sunset during the past year were examined, and the tendency of both phenomena to occur intermittently, but not necessarily simultaneously, was established, even though the transparency of air remained nearly constant.

On comparing these days with those on which Bishop's ring was stated to have been visible at Zurich, and with the dates, from M. Forel's paper, of abnormal sunset glows seen at Morges, it was found that the successive appearances of the respective phenomena occurred here about twenty days later than they did in Switzerland. Of course, the weather conditions at single stations introduce irregularities, so that the conclusion must be regarded as uncertain, but supposing it to be approximately correct, since the stations used lie nearly in the same latitude, and we can assume that the drift of the elevated dust-clouds was from west to east, their velocity in passing around the globe, from central Europe to the eastern United States, was about 30 miles per hour, or a rate considerably less than that found from trigonometrical measurements to be the velocity of the highest ice-clouds.

In the case of the great Krakatoa eruption in 1883, the speed of the ash-cloud as it circled the globe from east to west along the equator, and its slow diffusion toward the poles, was determined from the observation of the successive appearances of coloured suns and brilliant sunset glows in different parts of the world, collected by the Royal Society's committee appointed in 1884. The assistance in solving the problem of atmospheric circulation which a knowledge of the drift of dust ejected into the upper atmosphere by volcanoes situated in the tropics might furnish would certainly justify obtaining all available data bearing on the march of the abnormal sky colours. Mr. Clayton, of this observatory, began the collection of such data some time ago, but was deterred from continuing the work by reason of the difficulty in obtaining definite information. A task of such magnitude belongs properly to a commission possessing the necessary facilities for collecting and discussing the material, so it is hoped that an organisation like the Krakatoa Committee, the admirable report of which was published in 1887, may undertake the study of the recent and present remarkable sky colorations, probably occasioned by the eruptions in 1902 of the volcanoes in Martinique and St. Vincent.

A. LAWRENCE ROTCH.

Blue Hill Meteorological Observatory, Hyde Park, Mass., U.S.A., December 11.

Internal Oscillation in the Waters of Loch Ness.

I WOULD beg a little space in your columns to direct attention to some of the conclusions which I draw from temperature observations taken last summer in Loch Ness.

Routine observations have been taken at the south-west end of the loch several times a day since the middle of July, and I find that the temperature at any depth between 100 and 300 feet changes with time in a markedly periodic fashion, the duration of a period being approximately three days. At about 200 feet the difference between a maximum and a minimum is something like 5° F. At greater depths the temperature change is less, but of the same period and the same phase. At depths less than 200 feet also the temperature change appears to fall off in magnitude whilst retaining the same period and phase, but here there appear to be other changes more or less obscuring the simple periodic variation. Diagram 1 gives a few observations at 200 feet.

I conclude from these observations, and others taken at different parts of the loch, that there is an internal oscillation in the waters—an internal seiche, similar to the swinging which may be set up in the interface between oil and water lying the one above the other in a trough. For such a motion we require liquids of different density lying one above the other; in the loch the upper waters being warmer are lighter than the lower strata, and I think it probable that the region where the temperature changes most abruptly acts as a surface of separation, and is comparable with the interface between the oil and water in the simple arrangement just mentioned. In Diagram 2 I have tried to illustrate the motion. The shaded portion is intended to represent the warmer water, and the hard line the region where the temperature changes most abruptly. Rough calculations on the assumption that the swinging is of this nature give the period of the order observed. A very remarkable point is the large amplitude of the vibration. At the ends of the loch the isothermal surfaces suffering the greatest displacement may move through as much as 75 feet.

The observations make it probable that this swinging is started by gales and strong winds. Winds produce a slope of the upper isotherms down towards the lee end of the loch, and the stronger the wind the deeper is this effect felt. So that strong winds are able to displace the relatively deep

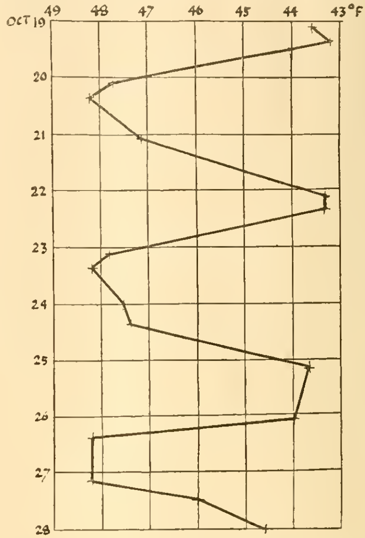

FIG. 1.

isotherms in that region where they act as an interface, and on the wind falling the isotherms swing back and continue to swing freely with a natural period.

Unfortunately it is necessary to wait for the return of summer before more observations can be made bearing on the subject, as the waters are now of almost uniform temperature.

I believe I am right in saying that such a phenomenon had up to this never been even suspected by limnologists.

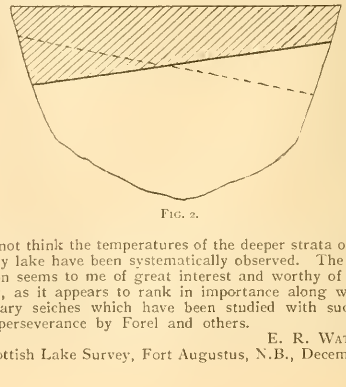

FIG. 2.

I do not think the temperatures of the deeper strata of water in any lake have been systematically observed. The phenomenon seems to me of great interest and worthy of careful study, as it appears to rank in importance along with the ordinary seiches which have been studied with such care and perseverance by Forel and others.

E. R. WATSON.

Scottish Lake Survey, Fort Augustus, N.B., December 12.

A GREAT RELIGION.[1]

If any proof were needed of the value of the comparative method in historic research, it is afforded by these handsome volumes. The science of comparative philology produced that of comparative mythology, and the establishing of a system of analytical study of myths and folklore, which extracted meaning from the meaningless, and turned the mere fable into precious fragments of historic record.

The study of myth and folklore revealed certain laws that were common to most systems by which the growth and development of a religion could be studied. First, it established the fact that a religion, be it the most elementary beliefs of a savage people or the fully developed creed of dynastic Egypt or Chaldea, or the sacerdotal system of the Hebrews, was essentially the product of the human mind—religion becomes, therefore, a branch of anthropology, and requires to be studied by the methods of that important science.

No religion of the ancient world so much demands to be studied by the anthropological method as that of Egypt. Its antiquity far exceeds that of all other nations, for many of its component elements belong to the prehistoric age. Viewed as a whole, it is a perfect conglomeration of strange and contradictory elements. Grossly savage beliefs of animal worship and cannibalism are found side by side with the most simple monotheism, and magic and demonology with an elaborate system of eschatology which in the latest times exercised a powerful influence on that of Christianity. Not only was the student faced with this confusion of elements, but there was another serious difficulty to encounter. Unlike the great Aryan or Semitic religions, the Egyptian religion possessed no canonical books like the Vedas or Avesta or the Hebrew scriptures. The Egyptians were not a literary people; there was a scribe caste, powerful through its priestly and official associations, but essentially a caste. Unlike the Babylonians, they had no national epic poems, no exegetical literature.

The only work which in any degree could be considered as the sacred book of the Egyptians was the "Book of the Dead," a mosaic of material of various ages and sources. The student, therefore, who would solve the riddle of the Sphinx and reduce chaos to system and order, must be a bold man, and prepared to face much labour and study. Great scholars had already laboured in the field. Dr. Heinrich Brugsch, in his work "Religion und Mythologie, der Alten Ægypter," had attempted to set forth the chief features of this wonderful religion; he had, however, been hampered by his material. The fine editions of the "Book of the Dead," such as the Ani and Nu papyri of the Theban age, were unpublished, and he had recourse chiefly to late material of the Ptolemaic age, a time when the Egyptians themselves knew little of their own religion. Moreover, Brugsch approached the subject from a classical, Aryan, and philosophical point, a method totally unsuitable for a religion with an African vocabulary. As Dr. Budge justly remarks, "No African language is suitable for giving expression to theological and philosophical speculations, and even an Egyptian priest of the highest intellectual attainments would have been unable to render a treatise of Aristotle into language which his brother priests without teaching could understand." M. Maspero was the next savant who essayed the task, and he had older material, and was the first to apply the anthropological method. He recognised the savage cults in animal worship and magic, and in the pyramid texts of the sixth dynasty.

The astonishing progress of discovery in Egypt during recent years has given an enormous retrospective enlargement to our knowledge of human life in the Nile Valley. Not only is the historic age known with an astonishing degree of detail to its very threshold, but our knowledge now extends far into the dark regions of the prehistoric.

From the graves on the edge of the Lybian plateau we gather not only the records of the life on earth of these people, but also the evidence of their simple creed and hopes of a life hereafter. Here, then, we must look for the beginnings of the religion of Egypt and the birth of the gods. It is now possible to ascertain the conditions of the environment in which the first elements of Egyptian religion grew up.

At the commencement of his work Dr. Budge deals with one of the greatest difficulties of the Egyptian religion—the problem of animal worship. At the time of man's first advent into north-east Africa and the Lybian plateau, the Nile valley presented a very different appearance from that of to-day. Banked by the Arabian and Lybian hills, the latter wooded and swarming with animals, and with great swamps and marshes full of Amphibia and serpents, &c., it was very different from the Egypt of historic times. Man found himself compelled to struggle for existence, not only with human foes, but also with a host of hostile animals. The fear of these produced a worship of them; we have a similar cult in Chaldea in the animal demons, lions, leopards, serpents, scorpions, &c. Man, however, soon demonstrated his superiority to the brute creation; some he killed in self-defence, some he domesticated or rendered serviceable to himself. The Egyptian of these prehistoric times was a cannibal; proof of this is shown by the long and valuable passage describing King Unas hunting, killing and eating the gods. Dr. Budge clearly shows the argument on which cannibalism was based. By eating the hearts and livers of men or gods the king acquired their powers; so also with animals. How early the Egyptian attained to the idea of some immortal element in man we cannot say, but we can see from the burials of the Neolithic age that it was fully developed then. This developed the belief in the god-man or god-king who lived and died and became immortal. He had as Unas the powers of man and of animals, and thus man worship and animal worship were fused by placing the animals' heads on human bodies, as the Babylonians placed human heads on animal bodies. The belief in the god-man—the anthropomorphic cult became the indigenous creed of Egypt—in the form of the worship of Osiris, and Dr. Budge's arguments for its north-east African origin are most convincing. Whatever other forms of religion were developed in Egypt or introduced from without, it remained the faith of *the people*, and continued so until the god-man Osiris became absorbed into the man Jesus Christ. It was the golden thread which ran through the tangled skein of religious life in Egypt for many thousands of years. In elucidating this fact, Dr. Budge has, as it were, established a base line for his study of all the other varied elements in this complex creed. These most important other elements are fully dealt with, but space will only allow us to deal with two, the Ra cult of Heliopolis and the worship of Horus the Hawk, "sky god" and "his blacksmith followers" with its centre at Edfu.

The solar cult of Ra-Tem of Heliopolis shows many traces of affinity with the solar cults of Asia, and this may be accounted for by the position of Heliopolis, but there is a preponderance of native elements. By many it has long been regarded as *the* religion of

[1] "The Gods of the Egyptians: Studies in Egyptian Mythology." By E. A. W. Budge, Litt D., D.Litt., &c., Keeper of the Department of Oriental Antiquities in the British Museum. 2 vols. Pp. xvii+525 and viii+431; with 98 coloured plates and 131 illustrations. (London: Methuen and Co., 1904.) Price 3*l*. 3*s*. net.

Egypt, owing to the immense power it attained when blended with that of Amen of Thebes, and administered by the most powerful priesthood the ancient world ever produced. Dr. Budge, however, very clearly demonstrates its position as the religion of the court and aristocracy of Egypt, as that of Osiris was the creed of the people. From an early period there was a fusion of the two creeds, and with the Theban school this was carried to the extreme, where Amen Ra assumes the function of Osiris and all the other gods as well, but with the fall of the ambitious hierarchy the old creeds once more asserted their power. This portion of the book is a most interesting and valuable account of one of the greatest religious movements of ancient times.

The revival of the Heliopolitan ritual, and especially the teaching as to the Heaven of the victorious Osirian, is very fully described, and there is here matter of immense value. Here the deceased who has become justified "becomes god the son of god," he takes his seat by the side of God, and eats of the Tree of Life, which is in the midst of the Field of Peace. He lives on light, becomes a being of light, and, as Dr. Budge points out and we must add very quietly, that as this cult was known among the people of Lower Egypt until two centuries after the Christian era, we have here the source from which the writer of the Apocalypse drew his description of the life of the Christian who had "overcome" the world. There is material under the study of the important mother goddess cults which should certainly attract attention from the New Testament critics, for here we have the basis of the Theotokos controversy. This is not the place to discuss theology, so we pass to the more interesting subject of the worship of Horus Beḥutet, the opponent of Set, with his curious guild of "Blacksmiths." Dr. Budge's remarks on this subject are of importance, as they show how often history is found interwoven with myth. Essentially a solar myth, there is interwoven with it the story of the invasion of Egypt from the south by a superior race who used iron or metal weapons against the flint weapons of the aborigines. To quote Dr. Budge:—

"It is of course impossible to say who were the blacksmiths that swept over Egypt from South to North, but the writer believes that they represent the invaders in predynastic times who made their way from a country in the East, by way of the Red Sea, by some road across the eastern desert. They brought with them the knowledge of working in metals and of brickmaking, and having conquered the indigenous people of the South, that is those around Edfu, made that city the centre of their civilisation."

In later times the material conflict was blended with the mythic, and hence the confused legend of Ptolemaic times. Sufficient has been said to show the rich material Dr. Budge has collected in these two great volumes, but we can only dip into them in this review. The valuable analysis which Dr. Budge gives of those strange works the "Book of the Tuat" and the "Book of the Pylons" will be welcome, for hitherto no authoritative English description of these works has been accessible. The curious illustrations of the journey of the sun through the night hours, which are found on the sarcophagus of Seti I. in the Sloane Museum and in the royal tombs of the nineteenth and twentieth dynasties, certainly depict all the horrors of hell to the simple and uninitiated. The works were, however, essentially sacerdotal, and inscribed in places not accessible to the people, so whatever their teaching might be, it did not affect the popular religion. Dr. Budge is probably right in denying the theory that the Egyptians believed in eternal punishment, but they supplied all the material for a most elaborate illustrated edition of the Egyptian inferno to those who held that doctrine. Hence we find the early Christians giving such vivid descriptions of the fate of the damned.

There are some points on which, however, we must differ from the author. After the very lucid description which he gives of the Egyptian Tuat or Land of Night, he gives us a most valuable excursus on the Hebrew Gehenna and the Babylonian Hell, and would attribute the Rabbinical ideas to Egyptian influence. Great as was the influence of Egyptian theology on early Christianity, the Apocalypse and Coptic writings, it is very doubtful if it attracted the Jewish mind. The Seven-headed Serpent of Revelation is the Serpent of the Week of the Babylonians with seven heads and tails—certainly not the seven-headed serpent of the Egyptians.

In conclusion, we must give a high word of praise to the preparation of the work; the beautiful plates and illustrations, the various tables and indices, render it a work that should win the gratitude of all Egyptologists, and add still more to the writer's reputation as an indefatigable worker and a painstaking scholar.

FIG. 1.—Horus of Beḥutet Armed (Edfu). From "Gods of the Egyptians.")

SCIENCE IN SOFT RAIMENT.[1]

IN these six agreeable volumes there is an extraordinary family likeness, which the authors themselves perhaps would be very unwilling to recognise.

[1] "Wild Nature's Ways." By R. Kearton, F.Z.S. With 200 illustrations from photographs taken direct from nature by Cherry and Richard Kearton. Pp. xvi+296. (Cassell and Co., 1903.) Price 10*s*. 6*d*. net.

"A Little Brother to the Bear, and other Animal Studies." By William J. Long. Illustrated by Charles Copeland. Pp xix+280. (Boston, U.S.A., and London: Ginn & Co., 1903.) Price 7*s*. 6*d*.

"Wee Tim'rous Beasties; Studies of Animal Life and Character." By Douglas English. With 150 illustrations from his photographs of living creatures. Pp. vi+223. (London: S. H. Bousfield and Co., Ltd., 1903.) Price 5*s*. net.

"Popular Natural History of the Lower Animals (Invertebrates)." By Henry Scherren, F.Z.S. Pp. 288; with 168 illustrations. (The Religious Tract Society, 1903.) Price 3*s*. 6*d*.

"Nature's Riddles; or the Battle of the Beasts." By H. W. Shepheard-Walwyn, M.A., F.Z.S., F.E.S. With coloured plate and over 100 illustrations by the author. Pp. xvi+295. (Cassell and Co., 1903.) Price 6*s*.

"Nature—Curious and Beautiful." By Richard Kerr, F.G.S., F.R.A.S. With sixty-nine illustrations from drawings made by the author. Pp. 274. (London: The Religious Tract Society, 1903.) Price 3*s*. 6*d*.

Even "the point of view," on which Mr. Long insists, does not very greatly vary. From book to book we come across the same animals, house-mouse and dormouse, sparrow and kingfisher, fox and squirrel, remarkable shells and strange leaf-insects. The problems are the same—the boundaries of instinct and reason, the methods and reality of protective resemblance, and all the general mystery of life. If Mr. Shepheard-Walwyn aims at inducing his readers "to study for themselves wild nature and her wonderful ways," Mr. Kearton makes the same appeal on his title-page. Mr. Walwyn gives his book an alternative title, "The Battle of the Beasts," his beasts proving in the sequel to be chiefly birds and insects. In like manner Mr. Douglas English chooses for one of his "wee tim'rous beasties" the purple emperor, although among butterflies *Apatura iris* is not tiny, and in Mr. English's own account of it is not timorous. He describes it as displaying while still a mere caterpillar "paroxysms of fury," and by help of its hard and formidable horns successfully repulsing the attacks of an ichneumon-fly. He leaves it to us in the end as a vision of triumphant beauty on its nuptial flight soaring boldly into the empyrean.

The three authors above mentioned compete with one another in a very delightful manner, their illustrations being evidently the result of extreme ingenuity and skill in the art of photography. Mr. Kearton and others are now making known the devices, sometimes rather comical, by which the wary children of the wilderness have to be outwitted. It is not so easy to win the grace of naturalness in the portrait of a willing sitter. One can scarcely, therefore, expect a cool and unconstrained demeanour from creatures shy and nervous, surprised in their most secluded haunts, and expecting only that they and their young ones are to be robbed and murdered by the camera-fiend. That centaur-like compound of man and machine has in consequence to manage its movements with consummate caution and hours of patience. The plan of stretching a wire, by stepping on which the wild creature will itself open the magic shutter, is no doubt hopeful. But there are ledges of precipitous rocks, accessible only at serious risk of life or limb, to which it is as difficult to attach an electric wire as to put salt on the tail of a hunted bird.

Fig. 1.—Dormouse. (From "Wee Tim'rous Beasties.")

The unelaborate care with which nature moulds and paints her savages, the mild and the merciless alike, so as to make them undistinguishable from their surroundings, has a singular effect on the pictorial success of a photograph. It might almost be said that the better it is the less we like it. The finish and excellence of the scene that is reproduced in all its minutiæ often beguiles the eye to such an extent that it becomes nearly as great a puzzle to find the bird, the nest, the caterpillar or the butterfly, the spider and the spider's web in the picture as it was to detect the real objects in their actual environment of reeds and moss and grass, dead leaves and bare twigs, or a medley of sticks and stones. In this respect Mr. Long in his humorous and entertaining book has a certain advantage. With the help of a clever artist he can make his incidents highly dramatic. He can emphasise what points he pleases in the life and actions of his coons and cats, moose and mink, fat familiar toad or woodcock with an astounding genius for surgery worthy of Hutton the bone-setter.

All the writers seem to agree in lamenting "That villainous saltpetre should be digg'd Out of the bowels of the harmless earth," to destroy their particular favourites, though they cannot help gloating over the hundreds of flies and other insects destroyed by toad or sparrow. But Mr. Long goes a step further in the cause of humanity. It is not only the ordinary gun of which he deprecates the use. The photographic gun must also be tabu. He celebrates the man "who goes to the woods for rest and for letting his soul grow," who is "content just to see and hear and understand," who "has no fret or sweat to get the sun just right and calculate his exact thirty-foot distance and then to fume and swear," as Mr. Long has "heard good men do" (though that, of course, is incredible and a mere aural delusion), "because the game fidgets, or the clouds obscure the sun, or the plates are not quick enough, or," &c. Thus do we scoff at other men's pursuits, and at our own! Mr. Kerr in turn might well laugh to scorn Mr. Long with his canoe and his camp, and his creeping up "through the brûlée to where bear and her cubs are gathering blueberries in their greedy, funny way." What if they should suddenly take a fancy to gathering Mr. Long?

Mr. Kerr says of his own excellent studies, "wherever possible I have made my sketches direct from Nature," with this ingenuous finish to the sentence, "and for this purpose I have spent many hours in the Natural History Museum, Cromwell Road." There, to be sure, no living bears are likely to quicken the pulse or to make the directness of nature-study over exciting. But in compensation, as Mr. Kerr's book will help its readers to perceive, our National Museum contains many of the most wonderful specimens that the globe produces, and though the game is dead and the life is still, they are trophies of all that is most artful and most artistic in nature's handiwork. If, however, the illustration of the watering-pot shell is faithfully reproduced, the example copied cannot be a very good one, since it shows far too faintly the two rudimentary embedded valves to which attention is directed in the text. Protective resemblance is finely exemplified in Mr. Kerr's figure and description of the leaf-butterfly, Kallima, from Mr. Rothschild's museum at Tring, and again by several figures of moths and butterflies in Mr. Walwyn's "Riddles." On the other hand, this much debated hypothesis is ill supported by the unnamed "submarine shellfish" in the latter work. There a species of Pteroceras is represented, a moderately flattened shell with seven long projecting processes, and Mr. Walwyn asks us to believe that this "mimics a crab, whose coat of mail affords him a very complete protection." The author does not trouble himself to say what crab is mimicked, or whether its coat of mail is harder than that of the Pteroceras, or anything like as hard. He does not say whether he ever saw a crab with its legs sprawling about in such impossible positions as the processes of the shell would represent. Above all, he seems to have forgotten that to look like a crab is the worst possible disguise to assume in the sea, unless you wish to say to the first passer-by that has a wide enough mouth, "please, come and eat me."

Mr. Henry Scherren's attractive and compendious little book stands rather apart from the rest. It aims, and aims successfully, at giving the young naturalist a pleasant idea of the invertebrates as a field of study. It is unfortunate that a wrong adjustment of the type on p. 49 has obscured the grouping of the cephalopods. The passage reads as if the second group no less than the first was subdivided into eight-armed and ten-armed species. The confusion is increased by a further accident on the following page, where the name of "the Pearly Nautilus" is attributed to the figure of "the Paper Nautilus," *Argonauta argo*, although it is

Fig. 2.—The Leaf-Butterfly. Rothschild Museum. (From "Nature—Curious and Beautiful.")

properly given later on to the *Nautilus pompilius* figured and discussed on p. 56. Such mistakes are likely enough to arise so long as publishers entertain a superstitious dread that the popularity of a book will be impaired by the introduction of technical scientific names. Alone among our authors, Mr. Kerr has been allowed to set this superstition at defiance. The public are seemingly expected to hail with delight such names as Mooweesuk and Musquash, and Chigwooltz and Unk Wunk. Perhaps they are pleasantly resonant of Longfellow's "Hiawatha." Otherwise they are no easier to remember than Linnean Latin. Mr. Long understands this, and kindly supplies a glossary, not of technical names, but of Indian and English. Hence we learn that Mooweesuk is "the coon," and that Nemox is "the fisher," but whether the world has more than one coon or more than one fisher we are left wondering, and what in the world Mr. Long's "fisher" may be remains a problem, one of nature's riddles for Mr. Shepheard-Walwyn to solve.

It may be said of all these books, though their merits are various and their individual merit unequal, that they are good both to give and to receive.

T. R. R. S.

INDIAN METEOROLOGICAL MEMOIRS.[1]

IT was only quite recently that there was noticed in these columns the volume containing the record of rainfall of each Indian station, printed in such a form that the reader could at a glance see the monthly, yearly, or monsoon fall for any year up to 1900. This important volume, published under the direction of Sir John Eliot, is now followed by another equally valuable, embodying all the pressure observations of each station for the whole period of observation up to the end of the year 1902. These pressures are all reduced to 32° F. and constant gravity (lat. 45°), but not for height above sea-level; the elevation of the cistern is, however, added in each case.

Previous to the year 1889, the monthly means given are those of the mean of the ten and sixteen hours' monthly mean, but after that year the 8 a.m. monthly values alone are employed. At the foot of each table the necessary information is given for converting one series into the other, so that no difficulty should be encountered in this respect.

As an indication of the thoroughness with which this compilation has been attended, the attention of the reader may be directed to appendix i., which contains notes on the positions of the observatories and the character of the barometric observations. Appendix ii. includes further important data, for here are collected for each station such valuable notes as makers and kinds of barometers employed, periods of use, positions, corrections to Calcutta standard, &c.

The data included in this volume refer to 121 different stations, and the records in most instances date from the year 1875.

Another memoir that has just recently been published is one which deals with the movements of the upper clouds. The observations were made at six stations, namely, Simla, Lahore, Jaipur, Allahabad, Vizagapatam, and Madras, and were recorded by means of Fineman's nephescopes, a description and illustration of which are given in the text.

The period of observation extended over the years 1895–1900, and in this volume not only is a monthly summary of the data for each of these stations inserted, but also the results of a brief discussion, and a series of twelve plates illustrating the mean directions of the different classes of clouds for each month of the year.

The following are among the chief results which have been gathered from this series of observations, but it is pointed out that a more extended series at

[1] Vol. xv., part i., Brief Discussion of the Cloud Observations Recorded at Six Stations in India. Pp. 112. Vol. xvi., part i., Monthly Normals of Air Pressure Reduced to 32° F. and Constant Gravity 45°. Pp. 184. (Published under the direction of Sir John Eliot, M.A., F.R.S., K.C.I.E., Meteorological Reporter to the Government of India and Director-General of Indian Observatories.)

twenty or thirty selected stations is desired to corroborate these facts and conclusions.

The amount of cirrus cloud is small during the rainy season in Upper India, and increases rapidly southwards, reaching a maximum in southern India.

The amount or frequency of cirro-stratus cloud is large in the dry season in northern India, and decreases rapidly southwards to southern India, where it is very small, as indicated by the Madras and Vizagapatam observations.

The amount of cirro-stratus is much smaller in the wet than in the dry season in Upper India. It is very small in the peninsula, almost as small as in the dry season. It is, on the other hand, of frequent occurrence over the area represented by Jaipur and Allahabad, and more especially in Allahabad.

Alto-cumulus cloud is a cloud of frequent occurrence in northern India throughout the whole year. It is of rare occurrence in the peninsula from November to May, and of occasional occurrence from June to October at Madras.

Cumulus and cumulo-nimbus are of frequent occurrence in the dry season at Simla, Jaipur, Vizagapatam and Madras, more especially at the two last-named coast stations, and are, in fact, the most characteristic clouds of the Indian area. They are of frequent occurrence in the wet season, more especially at the peninsular coast stations and at Jaipur and Allahabad.

It is noteworthy that cumulus and cumulo-nimbus are of much less frequent occurrence in the wet than in the dry season at Vizagapatam and Madras. The former type of cloud is also comparatively rare at Allahabad and the latter type of cloud at Jaipur in the dry season.

With regard to the directions of movements of the different types of clouds at the different seasons of the year, the maps in the volume illustrate the results most clearly. Reference may here, perhaps, be made only to the directions of the cirrus and cirro-stratus during the wet and dry seasons, and the following table sums up the information for the six stations.

Station	Mean direction of movement in			
	Dry Season		Wet Season	
	Cirrus	Cirro-stratus	Cirrus	Cirro-stratus
Simla	S. 80° W.	S. 82° W.	S. 85° W.	S. 69° W.
Lahore	S. 86 W.	S. 86 W.	S. 48 W.	N. 81 W.
Jaipur	N. 86 W.	N. 87 W.	N. 78 W.	N. 80 W.
Allahabad ...	S. 82 W.	S. 83 W.	N. 83 W.	S. 65 W.
Vizagapatam...	S. 4 W.	S. 27 W.	N. 72 E.	N. 65 E.
Madras	S. 13 W.	S. 86 W.	S. 82 E.	N. 87 E.

It will be seen that the movements of the two kinds of clouds in both seasons are practically the same in Upper or north-west India, but differ very considerably when the stations are more south.

It may further be noted that in the more northern stations the air movement as observed by the upper clouds is very steady in the direction from almost due west to east, and this is more especially so during the dry season from November to May.

During this small number of years of observation it was detected that the mean direction of the cirrus movement varied slightly in the same months or seasons of different years. This variation, as Sir John Eliot states, is almost certainly real, and represents a phase in the upper air movement over a considerable area.

Previous to these cloud observations it had been estimated on theoretical grounds that the south-west monsoon currents reach up to an average elevation of 10,000 to 15,000 feet, no actual measurements having been made. Sir John Eliot here points out that the most remarkable feature of the present cloud observations is the great variability or unsteadiness of the cloud movement during this period up to the elevation of the highest cirrus at Allahabad, in the centre or axis of the trough of low pressure. From cloud measurements made by photogrammeters at Allahabad during the wet seasons (June to September) of the years 1898 to 1900, it was deduced that the variable or unsteady movement in the monsoon trough extended "to a probable elevation of 30,000 feet at least, and perhaps even to 40,000 feet, and that the regular movement in the higher atmosphere from west to east is either suspended or occurs at a much greater elevation than in the dry season."

The important results obtained by determining the movements of the air currents at different heights by means of the observations of clouds indicate that the use of kites and unmanned balloons will perhaps prove a valuable auxiliary.

The appearance of these two important memoirs so recently after the one to which reference has already been made will give the reader some notion of the activity displayed by the Indian Meteorological Department under the distinguished direction of Sir John Eliot, and of the valuable researches which it contributes to meteorological science.

W. J. S. L.

THE FOOD AND DRUGS ACTS.[1]

THE two Parliamentary papers mentioned below, although widely different in character, are, at bottom, intimately connected with a common question, namely, the effective administration of the enactments dealing with the adulteration of food and drink.

The Food and Drugs Acts are now upwards of a third of a century old. They have been considered and reconsidered by Parliament at various times even down to the year 1899, and in the consideration have had to run the gauntlet of much deliberate obstruction from faddists, federations, and that class of free-fooders which regards any legislative interference with the buying and selling of anything of the nature of food, however bad, as noxious economic heresy, and a restriction of the free play of competition. That the Acts contain compromises, inconsistencies, and anomalies is well known to those who have anything to do with their administration. Nor has the judge-made law by which these anomalies have been interpreted tended to their smoother working; indeed, it has caused them to be absolutely inoperative in certain directions. How imperfect the Acts are is strikingly exemplified in the two papers before us.

The first, and in a sense the most important, of these is the final report of the Royal Commission appointed to inquire into arsenical poisoning from the consumption of beer and other articles of food or drink. It will be remembered that in the latter part of 1900 there occurred a serious epidemic of poisoning which was traced to arsenical contamination of beer at numerous breweries through the use of brewing sugars manufactured by a single firm in the neighbourhood of Liverpool. The arsenic was introduced into these sugars by way of a highly arsenical sulphuric acid supplied by a firm of chemical manufacturers in

[1] Final Report of the Royal Commission appointed to inquire into Arsenical Poisoning from the Consumption of Beer and other Articles of Food or Drink. Parliamentary Paper. Cd. 1848. 1903.

Final Report of the Departmental Committee appointed by the Board of Agriculture and Department of Agriculture and other Industries and Technical Instruction for Ireland to inquire and report upon the desirability of Regulations under Section 4 of the Sale of Food and Drugs Act 1899 for Butter. Parliamentary Paper. Cd. 1749. 1903.

Leeds which had been used in their production. This occurrence was attended with serious consequences, and caused such widespread alarm that it was deemed expedient that a Royal Commission should issue to ascertain the amount of the sickness and death attributable to poisoning by arsenic, and to consider by what safeguards the introduction of arsenic into articles of food or drink can be prevented.

In their first report the Commissioners dealt with the immediate question which led to their appointments, and made certain recommendations with the view of strengthening the hands of the Inland Revenue Authorities in preventing a recurrence of such a catastrophe as that which occurred in the autumn of 1900.

In their second and final report the Commissioners state in the outset what action they took to ascertain what became of the large stock (more than 700 tons) of arsenicated glucose and "invert" remaining at the works of the firm who made it, and also what became of certain arsenicated table syrups (14 tons in amount) which they had placed on the market. It is satisfactory to know that all the contaminated glucose and "invert" sugar was got rid of for purposes unconnected with food, particulars regarding each sale and the undertakings entered into respecting the use of all sugars sold being communicated to the Commission and to the Local Government Board.

As regards the extent of the epidemic, it appears from the evidence of witnesses and from information obtained from medical officers of health that the total number of persons who suffered was certainly not fewer than 6000, and probably considerably more. It is impossible to determine the number of fatal cases with any approach to accuracy. From the returns of the medical officers of health it appears that these were at least seventy, that is to say, there were seventy cases in which arsenical poisoning was entered in the death certificate as the cause of death, or was found to be a cause as the result of a coroner's inquest. These, in the opinion of the Commissioners, do not represent the total number of cases. Deaths occurring before the discovery of the cause of the outbreak were frequently certified as due to "chronic alcoholism" and "cirrhosis of the liver," and in some cases were attributed to Addison's disease and to locomotor ataxy. Other deaths were recorded as due to "alcoholic," "peripheral," or "multiple" neuritis

Not the least valuable result of the inquiry has been to bring together a series of detailed descriptions by competent medical observers of individual cases of poisoning, of different clinical types which they have distinguished, of particular symptoms met with at different stages of the malady, and of pathological changes observed *post mortem*. These descriptions form valuable material for reference and comparison, and merit careful attention.

The Commissioners are of opinion that a considerable proportion of beer brewed in some parts of the country before 1900 contained noteworthy quantities of arsenic, mainly derived from malt and from brewing sugars. It is also evident that before 1900 the degree to which beer had been liable to receive arsenic from malt must have varied greatly in different parts of England. Malt has been shown to have been subject to arsenical contamination in much greater degree when the fuel used on the kiln has been gas coke than when oven coke or anthracite has been employed. It would seem that the fact of greater prevalence of alcoholic neuritis among beer drinkers in Manchester and Liverpool before 1900, when compared with other places, is to be ascribed to the larger proportion of arsenic contained in much of the malt there used, due to the character of the fuel employed in kilning. That malt of this character will give rise to arsenical poisoning was shown by the occurrence of an outbreak in Halifax in 1902, the circumstances of which were carefully inquired into by the Commission.

Incidentally, the Commission has accumulated interesting and valuable information on the question of individual susceptibility to arsenic, on the mode in which it accumulates in human tissues, and on the ways in which it is eliminated. Arsenic was detected in sweat, in the epidermic scales which are freely shed in the condition known as keratosis, in the nails and in hair. It appears that epidermic tissues, which consist principally of keratin, have a special affinity for arsenic, and that the effect of arsenic upon nerve tissue may be related to the fact that nerve sheaths consist largely of keratin.

With regard to the suggested relation between the disease known as "beri-beri"—a disease mainly characterised by peripheral neuritis—and arsenical poisoning, the Commissioners are of opinion that such clinical, etiological and chemical data as they have been able to collect lend no support to the idea of such relation.

Much of the evidence laid before the Commission related to the relative value of different methods of estimating small quantities of arsenic in brewing materials and in food and drink generally. Indeed, there has sprung up quite a plentiful crop of literature on the subject within the last three years, and one effect of the inquiry has unquestionably been greatly to improve our analytical methods of detecting and estimating minimal quantities of arsenic. On the whole the Commission is inclined to recommend the method of comparison of mirrors, obtained either by the so-called Marsh-Berzelius method or by the electrolytic method as worked out by a departmental committee appointed by the Board of Inland Revenue.

A considerable section of the report deals with the various ways in which foods are liable to become contaminated by arsenic, and the precautions which should be taken by manufacturers to exclude it. In the greater number of cases the introduction of arsenic would appear to be due to the use of mineral acids, more particularly sulphuric and hydrochloric acid, in the preparation of ingredients of food. Arsenic may also be introduced in the mineral or organic colouring matters which may be employed to "improve" the appearance of food preparations.

The subject of malt naturally receives much attention. Although the exclusion of small quantities of arsenic from it has proved to be a matter of considerable difficulty, it is satisfactory to know that all the evidence goes to show that it is now commercially practicable to produce malt which either may be considered free from arsenic or in which the amount of arsenic is certainly less than 1/250th grain per pound. Considerations of space preclude us from attempting to show how it has been proved that access of arsenic to malt may be obviated or diminished. No doubt this section of the report will receive from those commercially interested in the matter the attention which its exhaustive treatment merits.

In the concluding sections of their report the Commissioners deal with the present means of official control over purity of food, more especially in relation to arsenic, and discuss the general question as to what improvements are, in their opinion, needed in the official control over the purity of food.

As this is, perhaps, the most generally important outcome of their deliberations, and bears directly upon the question of the efficacy of the machinery which supervises the working of the Food and Drugs Acts, we propose to reserve the consideration of their recommendations to a subsequent article.

STATE AID FOR AGRICULTURE.[1]

MR. T. S. DYMOND, who has charge of the agricultural education in the county of Essex, has published a valuable little pamphlet on the State aid given to agriculture in Denmark and Hungary, two countries with which he is personally familiar. Both countries can show great gains to the farming industry during the past ten or twenty years, mainly the result of improved education and organisation, but they present an interesting contrast in the way the work has been done. In Denmark the initiative has come from the individual; the State has simply stepped in and assisted whatever institutions for education and research had been started by the people themselves. It is true the Government has founded and liberally endowed the Royal Agricultural and Veterinary College at Copenhagen, and also maintains the higher research stations, but to the cooperative societies and other commercial developments, which have done so much for Danish agriculture, it gives little or no direct help.

In Hungary the conditions are very different; the whole organisation has been created from above; not only has the State founded an extraordinarily complete department for education and research, but it has not hesitated to enter boldly into business and provide financial assistance to the farmers in distressed districts. It develops horse and cattle breeding by the help of great State farms, it has created a flourishing fruit industry, founded credit banks and cooperative societies, and generally adopted the "paternal" standpoint of fostering the farming interests wherever its assistance could be effective. Despite the great success of its efforts, Mr. Dymond considers that there are not wanting signs of State aid having gone too far in Hungary and having become State interference, resulting in a certain measure of discouragement to the enterprise of individuals.

Turning to our own country in the light of these examples, Mr. Dymond would limit the assistance of the State to education and research; the whole genius of the English farmer is opposed to State aid in his business matters. As Mr. Dymond points out, many parts of the country already possess considerable, if but slightly appreciated, facilities for agricultural education; farmers can get their sons educated at very low rates, their manures analysed, their seeds tested, they can obtain expert advice of all kinds as cheaply as in any foreign country. Only if you cross the county boundary none of these good things may be available, and an immense waste is going on through the want of system and the localisation in particular counties of the work that is being done.

Mr. Dymond argues for more central direction, and urges that the Board of Agriculture, which financially assists so much of the work, should assume a certain measure of control and bring the whole country into line.

Appositely enough, on the heels of Mr. Dymond's pamphlet comes the annual report of the Board of Agriculture on the distribution of grants for education and research in 1902–03. From this we learn that the Board gives substantial financial aid, 800*l*. a year with an extra 200*l*. for the maintenance of a farm, to seven colleges of university standing in England and Wales, and also grants smaller sums to eight other schools or colleges, the total expenditure amounting to 8900*l*. per annum. This, however, represents only a portion of the whole expenditure on these institutions; so far as can be made out from the report, the county councils concerned contributed 29,127*l*., which does not in all cases include capital expenditure and outlay on the farm. The total expenditure of all the county councils in England and Wales on agricultural education amounted to 87,732*l*. in 1901–02, and if we consider the distribution of this money, the manner in which comparatively minor matters, like poultry and bee-keeping and manual processes, bulk in the account, a very strong case is made out for more central control, for at present the Board of Agriculture only *inspects* the expenditure of one-third of the whole sum.

The weak side of the Board's outlay is seen in the "special grants for experiment and research." The total allotted is 864*l*. 6*s*. 1*d*.; is this magnificent sum to be taken as an index of the official opinion of the importance of English agriculture or of the value of research? The distribution, too, is curious; 225*l*. is for repetitions of Dr. Somerville's interesting "manure and mutton" experiment, 84*l*. 6*s*. 1*d*. is for trials of maize growing, 50*l*. for experiments on wheat; the Somerset County Experimental Farm, with the astonishing proviso that care shall be taken to keep records in future, gets 100*l*., as does the "Aberdeen Agricultural Research Association." Rothamsted, which we were told in the *Times* last year is being starved for want of funds, gets just nothing at all. There seems a want of proportion somewhere.

[1] "Continental State-aid for Agriculture." By T. S. Dymond. (Chelmsford, 1903.)
"Annual Report on the Distribution of Grants for Agriculture and Research in the Year 1902–3." (London: The Board of Agriculture and Fisheries, 1903.)

ROBERT ETHERIDGE, F.R.S.

IN the death of Robert Etheridge geological science has lost a distinguished worker who was actively engaged for upwards of fifty years.

Born in Herefordshire on December 3, 1819, he settled in early years in Bristol, and was for some time employed in a business house.

His scientific career commenced in 1850, when he was appointed curator to the Museum of the Philosophical Society in that city. This post he held for seven years, during which period he made himself thoroughly acquainted with the local geology, extending his observations into the region beyond Gloucester and Cheltenham, and becoming an active member of the Cotteswold Naturalists' Field Club. Through the influence of Sir Roderick Murchison (who had in 1834 published an "Outline of the Geology of the Neighbourhood of Cheltenham") he was in 1857 appointed one of the palæontologists to the Geological Survey, working at first under J. W. Salter, and assisting Huxley at the Royal School of Mines by giving demonstrations in palæontology.

In 1859 he published his first work, entitled "Geology: its Relation and Bearing upon Mining," being the substance of three lectures which he had delivered before the Bristol Mining School.

During the earlier portion of his service on the Geological Survey, he was occupied chiefly in arranging and naming the Invertebrata of the Secondary and newer strata, and after Salter had retired the Palæozoic fossils also came directly under his charge. Later on, when Jukes questioned the age and relations of the Devonian formation, Etheridge received instructions to re-investigate its palæontology and stratigraphical divisions, and the results of this arduous and important task were published in 1867 in a memorable paper "On the Physical Structure of West Somerset and North Devon, and on the Palæontological Value of the Devonian Fossils."

The list of his published papers is not a long one, but he contributed articles on the Rhætic beds of Aust, Westbury-on-Severn, Watchet and Penarth, and on the dolomitic conglomerate of the Bristol area. His work on the Geological Survey was mainly in the lists of fossils which he prepared for numerous memoirs

from 1858 to 1881. In 1875 he revised and edited a third edition of John Phillips's "Geology of the Yorkshire Coast." For many years he devoted all his spare time to the preparation of a list of British fossils, stratigraphically and zoologically arranged. Of this great work the first volume, dealing with the Palæozoic species, was published in 1888. Two other volumes, on the Mesozoic and Cainozoic fossils, have remained in MS. In all more than 18,000 species were catalogued.

In 1881 Mr. Etheridge, greatly to the regret of his colleagues on the Geological Survey, was appointed assistant keeper in the geological department of the British Museum, and this post he held with much advantage to that institution for ten years, when he retired from the public service.

He was elected a fellow of the Royal Society in 1871. In 1880 the Murchison medal of the Geological Society was awarded to him, and in the same year he was elected president of that Society. The two addresses which he delivered at successive anniversary meetings of the Geological Society were voluminous papers on the analysis and distribution of the British Palæozoic and Jurassic fossils.

These essays, which were based on his great catalogue, formed a foundation for a subsequent elaborate book (published in 1885) on "Stratigraphical Geology and Palæontology." This work, ostensibly issued as part ii. of a second edition of John Phillips's "Manual of Geology, Theoretical and Practical," was almost wholly re-written and very much enlarged by Mr. Etheridge, so that very little of the original text remained. No less than 116 tables of organic remains were incorporated, and very full particulars were also given of the strata in various parts of the British islands.

The stratigraphical knowledge which Mr. Etheridge acquired in his early days at Bristol, and afterwards with the field officers on the Geological Survey, qualified him to give expert advice on economic questions relating to coal, water-supply, &c. In consequence his assistance was frequently sought by engineers and others. During recent years he was engaged as geological adviser to the promoters of the Dover coal-boring, and was occupied on matters connected with it until but a short time before his decease.

A man of untiring energy and vigour, he seemed personally never to grow older, and it was not until lately that he lost his upright bearing, but he never lost the cheery, kindly disposition which endeared him to all his friends and associates.

He died after a few days' illness, the result of a chill, on December 18, soon after he had completed his eighty-fourth year. A good portrait of him was inserted by Lady Prestwich in the "Life and Letters of Sir Joseph Prestwich."

H. B. W.

NOTES.

It is announced that the committee of the Parisian Press Association has decided upon the award of the prize of 100,000 francs placed at its disposal by M. Osiris. The committee has resolved to divide this sum between the two inventions which have in recent times most contributed to the honour of French science. The sum of 60,000 francs has been awarded to Mme. Curie for the continuation of her researches into radium, and 40,000 francs to M. Branly for his labours in connection with wireless telegraphy.

The sum of 30,000 francs has been placed at the disposal of Prof. d'Arsonval by the *Matin*, of Paris, in order to enable him to continue his researches in connection with the properties of radium.

Among the numerous special kinds of radiation recently discovered, not the least interesting are the *n*-rays of M. Blondlot. These rays, which were first discovered in the radiations from incandescent bodies, pass readily through aluminium, glass, black paper, and other substances, but are arrested by lead or by moistened paper. They were at first studied by means of their action upon small electric sparks, but a more convenient means of observing them is due to their action upon feebly illuminated phosphorescent bodies, the luminosity of which is increased when the Blondlot rays fall on them. In a more recent paper, M. Blondlot has found that bodies in a state of strain, such as tempered steel and unannealed glass, give off these rays spontaneously and continuously at the ordinary temperature, and in the current number of the *Comptes rendus* M. A. Charpentier shows that these rays are also emitted by the human body, especially by the muscles and nerves. He points out that this effect may prove to be of the greatest importance in the case of the nerves, as up to the present no external reactions of the nervous system have been observed, and a new field of studies in physiology and medicine is thus opened up.

Dr. Osann, of Berlin, has been appointed professor of mechanics at Clausthal, and Dr. Kippenberger and Dr. Georg Frerichs have been appointed professors of chemistry in the University of Bonn.

The Venetian Academy of Sciences, Letters and Arts, offers prizes of 3000 lire under the Querini-Stampaglia foundation for monographs on the following subjects:—The lakes of the Venetian district, treated from a physiographic and biological standpoint; the works of Manuzi as a critic of Greek and Latin literature; the origins of Venetian painting; and advances in the projective geometry of algebraic surfaces of two dimensions in space of *n* dimensions. Under the Cavalli foundation, a similar prize is offered for an essay on the effects of modern social and economic conditions, &c., on landlords and farmers, with especial reference to the Venetian provinces. Under the Balbi Valier foundation an award of the same amount is offered for advances in medicine or surgery for the period 1902–3, and under the Minich foundation a prize of 3000 lire is offered for embryological researches on the development of the larynx, the trachea, and the lungs in vertebrates and birds. The last day for sending in essays for the Stampaglia prize, on the Venetian lakes, and the Balbi Valier and Minich prizes is December 31, 1903; for the remaining prizes the essays are due at the end of subsequent years.

In the course of excavations on the Lulworth Castle Estate, in Dorset, a number of bronze relics have been found, and have been sent to the Dorset County Museum on temporary loan. The most important object is a bronze sword, $24\frac{1}{2}$ inches long, and, though broken, it is in a fine state of preservation. Other relics are a socket celt, a gold or heavily gilt bronze finger ring, a socket gouge, a hilt of a sword, an object which is believed to be one of the fittings of a car, supposed harness fittings, and a bronze crook.

The following telegram was received from Mr. W. S. Bruce, leader of the Scottish Antarctic Expedition, at the offices in Edinburgh on December 17:—"Buenos Ayres. *Scotia* Stanley. December 2. Refitting here. Hydrograph surveyed 4000 miles unexplored ocean; 70° 25′ south, 17 to 45 W.; 2700 fathoms trawled there; wintered Orkneys; detailed survey. Mossman and five men continue first-class meteorological, magnetical, biological station. Ramsay died August 6. All others robust; *Scotia* splendid.

Bruce." This is the first official information which has reached this country from the expedition. Mr. Allan Ramsay was the chief engineer.

It is reported by Reuter's Agency that a scientific expedition, organised by the anthropological section of the St. Louis Exhibition, is about to leave England for Central Africa under the direction of Mr. S. P. Verner. With reference to his journey, Mr. Verner is stated to have said that in order to get at the aboriginal life as little changed as possible by civilisation, it is desired to go out of the track of previous explorers and of all settlers. The base of operations will therefore be from the capital of Chief Ndombe, paramount chieftain of the Lunda tribes, at the head of navigation of the Kasai River, the largest southern tributary of the Congo, from which place an effort will be made to penetrate the interior.

A despatch from Taganrog on December 15 states that the Sea of Azov has receded to such an extent during the past five days that the bed of the sea is visible for a distance of several versts. Taganrog is at the head of a bay of the extensive lagoon known as the Sea of Azov, and the depth of water in the roadstead is greatly modified by west and east winds. High winds are reported to have raised clouds of sand which have covered the town, and these are probably responsible for the exceptionally shallow water described in the despatch.

Mr. R. I. Pocock has been elected to the post of superintendent of the Zoological Society's Gardens in succession to Mr. W. E. de Winton.

Captain Stanley Flower, who was in England for a short time during the summer, has returned to his post at the Zoological Gardens, Giza, Egypt. He writes that the three specimens of the curious "shoe-bill" or "whale-headed stork" (*Balaeniceps rex*) received from the White Nile in 1902 are still in good health and condition in the Giza gardens. No living example of this rare bird has reached England since the arrival of Mr. Petherick's original specimens in 1860.

Mr. W. Eagle Clarke, of the Museum of Science and Art at Edinburgh, a well-known authority on the migration of birds, passed a month during the migratory season in September and October last on board the lightship on the "Kentish Knock," which is situated in mid-sea off the mouth of the Thames, about twenty miles from land. Mr. Clarke has made a series of valuable observations on the various birds which passed by the lightship during this period, and has obtained many specimens which were killed by flying against the lantern. A full account of Mr. Clarke's experiences will be published in the next number of the *Ibis*.

It is understood that the authorities of the British Museum (Natural History) and the director of the Geological Survey of Egypt have agreed to the preparation of a joint report on the wonderful discoveries of fossil animals recently made in the Fayûm. Dr. Andrews will proceed to Egypt early next year to examine and catalogue the specimens in the Geological Museum at Cairo, but will not attempt to make further collections. A fine example of the skull of the horned Arsinoitherium (perhaps the most remarkable of all these discoveries) is now exhibited in the central hall of the Museum at South Kensington.

Among the contents of the second part of the Bergen Museum *Aarbog* for 1903 is a paper by Mr. H. Broch on the hydroid polyps collected during the cruises of the exploring vessel *Michael Sars* in the North Sea from 1900 to 1902. Several new forms are named and described.

Mr. Ralph S. Lillie has found (*Amer. Journ. of Physiology*, viii., No. 4) that isolated cells and cell-nuclei suspended in cane-sugar solution through which an electric current is passed migrate in some cases with the negative, in others with the positive, stream. The majority of such structures migrate with the negative stream, and this tendency is especially strong in free nuclei and structures consisting chiefly of nuclear matter. Cells with voluminous cytoplasm, on the other hand, tend to move with the positive stream.

The violets of Philadelphia afford to Mr. W. Stone the text for an article on racial variation in animals and plants, which appears in the October issue of the *Proceedings* of the Philadelphia Academy. In the course of this article the author directs attention to the growing practice among American zoologists of discarding the use of trinomials, and classing as a species every distinct animal form, no matter how slightly differentiated. This usage, it is urged, receives support from the methods of botanical classification. Where is all this splitting going to end? is the question which naturally arises in the minds of old-fashioned zoologists.

The December number of the *Popular Science Monthly* contains two articles on biological subjects, the one, by Prof. T. H. Morgan, dealing with recent theories in regard to the determination of sex, and the other, by Dr. D. S. Jordan, on the salmon and salmon-streams of Alaska. Dr. Jordan recognises five species of Pacific salmon of the genus Oncorhynchus from these rivers, as well as three kinds of trout (inclusive of the now well-known rainbow-trout), and two other species belonging to other genera. As regards the salmon-tinning industry, the rivers of Alaska may be divided into three groups, king-salmon, red salmon, and humpbacked salmon streams. Those of the first class are the most important, but even these are less valuable than the corresponding rivers of British Columbia, owing to the fact that, from the shorter run, the fishes are nearer the spawning season when they enter, a larger proportion of them having white flesh in June than is the case with their Columbian brethren in August.

"The Geology of Worcester, Massachusetts," by Messrs. J. H. Perry and B. K. Emerson, has been issued by the Worcester Natural History Society (Worcester, Mass., 1903). It is a well illustrated work descriptive of the rocks and fossils of the county, and is written for those who have no technical knowledge of the subject. The interest is mainly petrological and mineralogical.

We have received the general report on the operations of the Survey of India during 1901–2, prepared under the direction of Colonel Gore, Surveyor-General. Work has been carried on in the United Provinces, and also in the Shan States and Burma. The question of the condition of the existing topographic maps of the country has engaged serious attention, and it is admitted that more systematic arrangements must be made for their revision.

The State of Indiana has issued in one volume (1903) the twenty-sixth and twenty-seventh annual reports for 1901 and 1902 of the Department of Geology and Natural Resources. Among the papers included is an important essay on the mineral waters of Indiana, by Mr. W. S. Blatchley, State geologist. He gives the location and describes the character of the waters of more than eighty wells and springs. Mr. Robert Hessler follows with an account of

the medicinal properties and uses of the waters. Mr. Blatchley deals also with the gold and diamonds of the State. Gold is widely disseminated in the Glacial Drift, but the occurrence of diamonds, which have been found while panning gold, is only of scientific interest. Mr. G. H. Ashley writes on the Lower Carboniferous area of southern Indiana, and directs attention to the economic products of the rocks, which comprise materials for good building stone, for the manufacture of Portland cement, and glass sands. There are also articles on the Orthoptera and Mollusca, and reports on the petroleum industry.

At the present time, when the British Cotton-growing Association is fostering the experiments which are being made to grow cotton in various parts of British Africa and in some of the West Indian islands, an account by the principal of the School of Agriculture in Cairo of the impressions gained during a visit to the cotton-growing States in America is particularly opportune. From a consideration of the principal characters of different cottons, and of the exclusive position which is held by Egyptian and South Sea island cotton, the writer shows that it is a matter of considerable importance to improve the quality as far as possible by taking advantage of selection and hybridisation. Practical suggestions are made with regard to the cultivation on the subjects of soil, planting, maturation of the seed, and rotation of crops.

Dr. Dixon has added to his contributions towards the elucidation of the mode of ascent of water in tall trees by suggesting a transpiration model, which is described in the *Scientific Proceedings* of the Royal Dublin Society. Over the top of a thistle funnel are fixed two parchment diaphragms converted into semipermeable membranes by soaking first in gelatin and then in tannin. These are arranged so as to leave a small space in which sugar is placed before closing up. A continuous column of water is established from the membranes through the funnel and connections, to a supply of water below. The water enters the artificial cell, fills it, and finally water and sugar soak through the outer membrane. The vapour tension of the water below the lower membrane is greater than that of the liquid in the cell, and the latter is greater than the vapour tension of the liquid above the upper membrane, so that a flow of water takes place from the reservoir upwards.

The *Transvaal Agricultural Journal*, which is issued quarterly, and has now reached its fifth number, serves to show with how much energy the Agricultural Department of the new colony, under the direction of Mr. F. B. Smith, is attacking the many problems of farming in that country. A more difficult task cannot well be imagined; the disasters of the war, which has denuded the country of its stock, have been accompanied by repeated attacks of epizootic diseases of all kinds, to which new importations of cattle succumb at once; at the same time the greatest drought since 1862 has occurred, and even Kafir labour has been forced up to a price prohibitive to the farmer. The numbers of the *Journal* bear evidence of the diversity and virulence of the diseases of stock that prevail; fortunately they show also that the Agricultural Department is busy with investigations on the origin of the diseases and the best preventive measures against them. The most dreaded diseases seem to be "red water" and the more recently discovered "Rhodesian red water" or "African coast fever," both of which are propagated by ticks as an intermediate host, but though animals get immunised or "salted" against the former, the latter seems invariably fatal.

Messrs. Macmillan and Co., Ltd., have published part v. of "A School Geometry," by Messrs. H. S. Hall and F. H. Stevens. This section contains the substance of Euclid Book vi., with additional theorems and examples.

Messrs. Dawbarn and Ward, Ltd., have added to their series of useful little "Rural Handbooks" a volume by Mr. H. Francklin on incubating and rearing utility fowls. The principles on which incubators and rearers are constructed are explained, and the advantages of artificial as compared with natural incubation are made clear.

A copy of the sixth edition of Strasburger's "Lehrbuch der Botanik" has been received from the publisher, Herr Gustav Fischer, Jena. The work has been completely revised, and many sections have been altered in order to adapt them to the present state of knowledge, especially in connection with plant physiology and morphology.

We have received the year-book of meteorological observations at the station of the First Order belonging to the *Magdeburg Journal* for the year 1900. This is the twentieth volume of the series, and contains, in addition to observations and results recorded in accordance with the international scheme, complete hourly readings and means, observations of earth temperature, evaporation, &c. As regards tabular statements of the results of a well equipped observatory, nothing better could be desired. The autographic registrations of a Campbell-Stokes sunshine recorder have been photochemically reproduced; the cards ranged side by side have a very neat appearance, and give a clear view of the amount of bright sunshine in the different months. During the seven months of April to October there were only thirteen sunless days.

The Christmas number of *Photography* (London: Iliffe and Sons, Ltd., price 1s.) is a production which will be heartily welcomed by those interested in the artistic side of photography. No pains seem to have been spared to render the book high class in every respect, and the thirty or more full-page and smaller half-tone reproductions from photographs printed on glazed art paper, and the letterpress and line drawings on rough antique paper, are sufficient proof of this statement. The contents of the letterpress consist of six articles on topics of widely different interest. Mr. F. H. Evans, on "The Characteristic Use of the Hands in Portraiture," gives some valuable hints on the conspicuous part played by the hands of sitters, and illustrates his remarks by photographs taken by himself. "Landscape in Pictorial Photography" is contributed by "Fecit," who in this delightful essay uses numerous illustrations of prominent photographers to elucidate his points. Other articles are "Photography in a Wood," by Mr. Will. A. Cadley; "W. Rawlings—a Photographer of Winter," by Monochrome; and, in a lighter vein, the "Walrus" gives an account of the weird inventions of "My Friend Choggles," and "Pettifer" prattles about his experiences of winter photography.

The report of the ninth meeting of the Australasian Association for the Advancement of Science, held at Hobart, Tasmania, in 1902, has now been published. The volume is edited by Mr. Alex. Morton, the secretary of the Royal Society of Tasmania, and runs to nearly nine hundred pages. The contents of the report, including as they do detailed accounts of the ten sections into which for working purposes the Association is divided, and reports of eight research committees, show conclusively that the Australasian men of science are following very successfully the example set by the parent association. The presi-

dential address for 1902, by Captain F. W. Hutton, F.R.S., dealt with evolution and its teaching. We have also received a copy of the Walker memorial volume published by the Royal Society of Tasmania, and containing the papers on early Tasmania read before the Society during the years 1888–1899 by the late Mr. J. B. Walker, vice-chancellor of the Tasmanian University.

The report of the U.S. National Museum for the year ending June 30, 1901, has just reached us from the Smithsonian Institution. Part i. of the volume (of 452 pages) contains the report of the assistant secretary and the reports of three head curators, a list of accessions to the museum, and a bibliography of the publications of the museum. The second part will, however, prove of more general interest, consisting as it does of five lavishly illustrated articles. These contributions are, first, a report describing the exhibit of the U.S. National Museum at the Pan-American Exposition at Buffalo in 1901, by Messrs. F. W. True, W. H. Holmes, and G. P. Merrill. This report is illustrated by seventy-two full-page plates, which it would be difficult to improve. Mr. W. H. Holmes also describes the flint implements and fossil remains from a sulphur spring at Afton, Indian Territory, this article being accompanied by twenty-six plates; and the same author deals with the classification and arrangement of the exhibits of an anthropological museum. Mr. Walter Hough discusses archæological field work in N.E. Arizona, and gives an account of the Museum-Gates Expedition in 1901, and with this monograph there are 101 plates, some of which are beautifully coloured. The last contribution is by Mr. J. B. Steere, and is a narrative of a visit to Indian tribes of the Purus river, Brazil.

A quantitative study by Dr. Paul von Schroeder (described in the *Zeitschrift für physikalische Chemie*) of the setting and swelling of gelatin has led to some interesting observations, which not only throw light on the phenomena of gelatinisation, but also form an important addition to our knowledge of reversible chemical changes. It appears that gelatin solutions undergo two types of change, a non-reversible hydrolysis by which the setting power of the solution is permanently impaired, and a reversible change as the result of which the jelly melts when heated and slowly solidifies when cooled. The setting power of a solution is accurately indicated by its viscosity. If after rapidly cooling from 100° the viscosity is measured at 25°, a low value is obtained which gradually increases until, if the decomposition of the gelatin has not proceeded too far, it culminates in the setting of the whole mass. By measuring the increment of viscosity during one hour it is possible to predict whether the solution will set in the course of the next twenty-four hours. The reverse process by which the gelatin swells and then dissolves in water presents similar points of interest. Gelatin saturated with water has a higher vapour-pressure than water itself, and loses weight in a saturated atmosphere; the difference of vapour-pressure is, however, very minute, and may be compared with that which exists between drops of different sizes, and causes the larger drops of a fog to grow at the expense of the smaller particles.

At a meeting of the Institution of Civil Engineers on December 15 several aspects of the important question of water supply were discussed. Prof. J. Campbell Brown read a paper on deposits in pipes and other channels conveying potable water. Analyses were given of incrustations on iron pipes, showing that these incrustations were due to oxidation of the iron of the pipes, whether wide-spread or in nodules, and that they were not limited to acid waters, but were common to acid, alkaline, and neutral waters. Investigations were recorded showing that slimy deposits on the inner surface of pipes, &c., were produced by gelatinous and filamentous iron-organisms which grew and extracted iron from the water, and died at one end while they grew at the other. Solid rock particles were entangled in this slime, and binoxide of manganese was deposited by chemical action, and this also was entangled in the mass of the gelatinous iron-organisms. Messrs. Osbert Chadwick and Bertram Blount introduced the subject of the purification of water highly charged with vegetable matter, with special reference to the effect of aëration. They showed that the purification of tropical waters was very difficult; they had found that treatment with iron was efficacious, but the treatment must be more thorough than with ordinary water-supplies. The character of these waters charged with vegetable matters rendered the removal of the iron difficult. Systematic aëration, so as to ensure an abundant supply of oxygen, was requisite. An apparatus had been devised in which the water was caused to flow through perforated plates, emerging in streams of small diameter and exposing so large a surface per unit volume of liquid that rapid absorption of oxygen from the air was made certain.

The additions to the Zoological Society's Gardens during the past week include two Malabar Mynahs (*Poliopsar malabaricus*) from India, presented by Mr. A. F. Vine; two South Albemarle Tortoises (*Testudo vicina*) from the Albemarle Islands, presented by the Captain and Officers of H.M.S. *Amphion*; two Hybrid Parrakeets (between *Palaeornis eximius* and *Psephotus haematonotus*), four Limbless Lizards (*Pygopus lepidopus*) from Australia, deposited.

OUR ASTRONOMICAL COLUMN.

Radial Velocities of β Aurigæ.—M. G. A. Tikhoff, of the Pulkowa Observatory, has recently concluded a research on the relative velocities of the spectroscopic binary β Aurigæ, and publishes his results in No. 3916 of the *Astronomische Nachrichten*.

The forty-one plates on which the results are based were obtained by M. Belopolsky, nineteen during the early part of 1902 with a Rutherford spectroscope, and twenty-two at the end of 1902 and the beginning of 1903 with a new Töpfer three-prism spectrograph. The relative velocities of the components are given in a table, which also shows the exact time at which the plates were taken and the interval since the last conjunction, and they show a maximum of 228 km. per second, on March 24, 1902, to zero.

The curve obtained on plotting these results gave 3d. 23h. 30·4m. as the period, and it also indicates that the system is not only a binary one, as announced by Prof. Pickering in 1890, but is made up of more than two bodies. This is confirmed by the spectrogram obtained on January 21, 1903, in which the line Hγ is made up of four components, indicating the existence of four separate bodies with different velocities.

M. Tikhoff has arrived at the conclusion that the system is made up of two pairs, each pair consisting of a star giving strong lines and another giving weak lines, and each element making a complete revolution about the centre of gravity of its pair in 19·1 hours. The ratio of the masses of the two groups is near unity, and the proper motion of the whole system as deduced from the magnesium lines at λ 4481 and λ 4352 is −16 km. per second. The epoch of conjunction may be taken as February, 1903, 3d. 10h. (Pulkowa M.T.).

The "Doubling" of the Martian Canals.—In discussing the instrumentality of "contrast" in producing the duplicated appearance of Martian canals, M. E. M.

Antoniadi directs attention to some experiments made by him which showed that when single, elliptical, dark spots were examined for a long unbroken period they appeared to develop a duplication similar to that observed in Martian phenomena. He also states that Schiaparelli repeatedly saw the well-defined dark seas with lighter interiors, and when the narrower seas, such as the Mare Cimmerium, Lacus Niliacus, and Sinus Sabæus were observed steadily for a long time, they manifested a tendency to beget islands which exactly resembled in shape the areas in which they appeared. M. Antoniadi directs attention to the fact that these islands always appeared to be surrounded by "dark canals," and he has therefore arrived at the conclusion that their appearance, and the apparent "gemination" of the canals, are simply results of the physiological effects of "contrast" (*Astronomische Nachrichten*, No. 3916).

OBSERVATIONS OF LEONIDS AND BIELIDS AT ATHENS.—In a communication to the Paris Academy of Sciences, M. Eginitis, director of the Athens Observatory, records the following observations of the Leonid and Bielid showers made at Athens during November:—

Leonids.—November 14, 11h. 50m. to 18h. (Athens M.T.), twelve meteors, appearing to emanate from radiants situated at $\alpha=152°$, $\delta=+25°$, and $\alpha=156°$, $\delta=+20°$, were seen.

November 15, 9h. 50m. to 17h. 50m., 187 meteors were observed from the following radiants:—$\alpha=150°$, $\delta=+22°$; $\alpha=153°$, $\delta=+21°$; $\alpha=152°$, $\delta=+24°$.

November 16, thirty-three meteors observed, chiefly from a radiant situated at $\alpha=150°$, $\delta=+17°$.

This shower appeared to attain its maximum between 15h. and 16h. on November 15. The general colour of the meteors was red, their velocities moderately swift, and their mean brightness equivalent to the fourth magnitude.

Bielids.—A watch was kept for this shower on the evenings of November 22, 23 and 24, but no meteors were seen on November 22, possibly because the sky was very hazy.

From 7h. 46m. to 16h. on November 23, fourteen meteors were seen, chiefly emanating from a radiant situated at $\alpha=23°$, $\delta=+43°$. On November 24 eleven meteors were observed, and these indicated the existence of two radiants, one at $\alpha=26°$, $\delta=+46°$, and the other at $\alpha=26°$, $\delta=+43°$.

In general the Bielids were red in colour and equivalent in brightness to the fifth magnitude stars; they moved so swiftly that their very short paths were hardly visible (*Comptes rendus*, December 7).

THE HIGHER EDUCATION OF WOMEN.

THE adequate provision of secondary and higher education for English girls and women is to be regarded as one of the accomplishments of the latter half of the nineteenth century. In 1850, for instance, the popular idea here and elsewhere was that women were intellectually incapable of benefiting by higher instruction. To quote Dr. Leslie Waggener, of the University of Texas, "it was seriously questioned whether the 'female' mind could untangle the intricacies of pure mathematics, could appreciate the abstruse speculations of metaphysics, or could follow, step by step, the inductions of a scientific investigation." Fifty years' experience has, however, demonstrated the complete fallacy of this preconception. Speaking at the Cambridge University Extension summer meeting in 1900, Mrs. Henry Sidgwick, principal of Newnham College, said of higher education for women, "I do not think its desirability is any longer seriously doubted by anyone who has looked into the facts, and whose opinion on the question is worth considering." Similarly, President Eliot, of Harvard College, in an address in 1896, referring to the university over which he presides, remarked, "it is a quarter of a century since the college doors were opened to women. Since that time, where girls and boys have been educated together, it has become an historical fact that women have made rapid strides, and captured a greater number of honours in proportion to their number than men."

So complete a change of opinion on a subject of such importance as the suitable education of the larger half of the human race deserves attention, and the steps in the movement which has resulted in the recognition of the claims of women at most universities throughout the world, supply a profitable study for all students of educational problems. A comparison, too, of the present provision of university courses for women with their complete non-existence in 1850 should serve to cheer those men of science and others who are endeavouring to improve our national education in other directions. It is gratifying, in beginning a brief historical summary of the growth of the movement to provide secondary and higher education for women, to be able to state that among the first efforts in this direction were those made in England. The absence of public secondary schools for girls in this country, and the impossibility of obtaining really educated governesses, were the causes which led the late F. D. Maurice and others to work with the Governesses' Benevolent Institution to improve matters, and the labours of these pioneers led to the establishment, in 1848, of Queen's College, London, the original object of which institution was to train women teachers. In the following year Bedford College, London, was founded, and so successful has it been that it is now one of two colleges for women which are constituent colleges of the reconstructed University of London. A good start having been made, the movement grew and ere long flourished greatly in several localities. The North London Collegiate School for Girls was established by Miss Frances Buss in 1850, and the Ladies' College at Cheltenham in 1853. The thorough education of the daughters of middle-class families had become sufficiently general in 1863 to convince the University of Cambridge of the advisability of at least trying the experiment of admitting girls to the local examinations conducted by them in various centres throughout the country, and in 1865 girls were formally admitted. Then came the Schools Inquiry Commission of 1864, which, after sitting for three years, reported at the end of 1867. Ladies were called upon by the Commission to give evidence as to the provision for the secondary education of girls, and, to quote Mrs. Henry Sidgwick again, "The assistant commissioners, who had examined and reported on the condition of secondary education in various districts, gave a deplorable account of the insufficiency of the girls' schools, and of the immense difficulty of finding any adequately-educated female teachers for them." In 1872, the National Union, under the presidency of Princess Louise, was started to reform girls' education. This association soon established the Girls' Public Day Schools Company, and at present, this company alone, has 34 schools, about 7000 pupils, and about 600 teachers of different grades.

This cursory glance at the history of the attempts made to supply English girls with secondary education is necessary, because the need created by the establishment of these schools for highly qualified women teachers directed attention to the necessity for the provision of higher education at English colleges and universities, a need which had hitherto been completely ignored. The recognition of the claims of women to as much education as they desire has in England been brought about gradually, and it will be convenient to indicate the more important steps taken since the foundation of Queen's College, London, in 1848, and then to outline, as exactly as possible, the present state of things in other countries. It will simplify matters, too, to deal with different countries separately, and to take the universities of Great Britain and Ireland first, and in most detail.

GREAT BRITAIN AND IRELAND.

Special lectures for women were started in connection with the University of Cambridge in 1870. Girton College was incorporated at Cambridge in 1873, though it had been in existence at Hitchin since 1869, and from its inauguration had prepared its students for the examinations of Cambridge, where women were first informally examined for the previous examination in 1870, and for the tripos examination in 1872. Girton was "designed to hold in relation to girls' schools and home training a position analogous to that occupied by the universities towards the public schools for boys." In 1871, a house of residence for women attending university lectures was opened in Cambridge, and this institution became known, in 1875, as Newnham Hall, and was constituted a college in 1880. In the same year as Newnham College was incorporated, the uni-

versity appointed a syndicate to consider the question of conferring degrees on women, with the result that in 1881, though degrees were refused, formal admission for women to the previous and tripos examinations was granted. And up to the present time the privilege of receiving degrees is withheld, though women are admitted by courtesy to almost all lectures. A syndicate appointed in 1896 recommended that degrees be conferred by diploma without permitting admission to membership of the university, but the proposal was rejected by the Senate in 1897 by 1713 votes to 662. The concession of 1881 still regulates the admission of women to the examinations of the university. In order to be permitted to take the tripos examinations women must reside at Girton or Newnham, and admission to these colleges is only granted to students who have passed the previous or some other recognised examination. A class list of female students is published after the examinations, along with the list of members of the university; the method of arrangement is the same in both cases, and certificates are given to women stating the class or place in class attained in each examination.

At Oxford, lectures and classes were started for women in 1873, and examinations were instituted for them two years later. An association for encouraging the education of women was formed in 1878, and is still in active existence. Through the secretary of the association women are admitted to nearly all the lectures given in Oxford, and the council of the association registers all women students. These students are either in residence at Somerville College (founded 1879), Lady Margaret Hall (1879), St. Hugh's Hall (1886), St. Hilda's Hall (1893), or belong to the Society of Home Students, comprising students who reside in private families and are supervised by the council of the association. In 1884, honour moderations and final honour schools of mathematics, natural science, and modern history were opened to women, and from time to time admission to the examinations of other schools was granted, but it was not until 1894 that they were free to present themselves for examination in all the subjects in which men may take the B.A. degree. Women are not eligible for degrees. Congregation rejected a proposal, in 1896, to admit women to degrees or to grant them diplomas recording their success in the final schools examinations. An important difference between Oxford and Cambridge is that at the former, university women are admitted to the pass as well as to the honour schools, and for either examination; an outside student is equally eligible with those who have studied and resided at Oxford.

As regards the extent to which women avail themselves of the facilities offered by the Universities of Cambridge and Oxford for their higher education, it may be said that, during the session 1901–2, Girton and Newnham together had 292 students, while in 1902 there were at Oxford 228 registered women students. The whole number of women students who took honours in the various triposes at Cambridge from 1881, the year in which they were opened to women, to 1900 was 1036, and of these 180 took honours in natural science, the numbers in mathematics being 250 and in classics 227.

The University of London, which received its first charter in 1836, was the first English university to recognise the claims of women. In 1867 the university was granted a supplementary charter, under which it was enabled to offer certain special certificates to women. In 1880 women were admitted to all the degrees, honours, and prizes which were at the disposal of the university, and in 1882 women graduates were admitted as members of convocation.

The University of Durham, by a supplementary charter granted in 1895, opened all its degrees except those in theology to women. Women are admitted to university lectures on the same conditions as men, but to qualify for the degrees women must reside at Durham in the women's hostel provided by the university.

The University of Wales, which came into existence under the charter of 1893, admits women to its examinations and degrees, as members of the university, on the strictest equality with men, and women are equally eligible for any office created by the university. Much the same is true of the recently constituted universities, such as those of Birmingham and Liverpool, and at the university colleges throughout the country no distinction is made between the sexes.

So far as the Scottish universities are concerned, that is to say, the Universities of Aberdeen, Edinburgh, Glasgow, and St. Andrews, it is only necessary to say that the Universities (Scotland) Act, 1889, included a provision "to enable each university to admit women to graduation in one or more faculties, and to provide for their instruction." An ordinance to this effect was passed in 1892, with the result that women are in every case admitted to the degrees in arts, science and medicine, and at Aberdeen to the degrees in law. The university lectures are, as a rule, open to women, but in some cases separate instruction is provided for them.

Despite current rumours, there are at present in Ireland but two universities, Dublin University, or Trinity College, Dublin, and the Royal University. The admission of women has been approved by the council of Trinity College, and a recommendation was brought before the Senate on June 9 of this year and sanctioned by an overwhelming majority. In the case of the Royal University of Ireland, which, like the old University of London was, is purely an examining body, all degrees, honours, scholarships, and even junior fellowships are open to students of either sex, and candidates for medical degrees alone are required to pursue fixed courses of study at special colleges.

Before reviewing the regulations for the admission of women to continental universities, a digression, interesting at least to men of science, may be permitted. What is the character of the education given in schools for girls by the women who have had the advantages resulting from the concessions now described? What part does science take in the curricula of the schools administered by university women? It may at least be said that it is becoming increasingly understood that household management is a branch of applied science; cookery and laundry-work are, in some quarters at least, recognised as applications of chemistry to domestic needs; and hygiene and physiology are appreciated to some extent as the foundations upon which the arrangements for the health of the home should be based. But the adherence to these commonplace truths is still too much a matter of theory, and the present methods of teaching in girls' schools are based almost exclusively upon what has grown up in the schools for boys. Prof. Armstrong, at this year's meeting of the British Association, offered a strong protest in this connection. He said, "When I consider what my own children have done at school, what girls generally are doing, I am in despair—the training is so hopelessly unpractical, so academic, so narrow in its outlook. There is so little insight and originality displayed by women in diagnosing and providing for women's requirements; female educators are so obstinate and difficult to persuade, so limited in their conceptions." More recently that vigorous and brilliant author, Mrs. F. A. Steel, has written: "Read through, for instance, the Education Act—new or old does not matter, since any Education Act I have ever heard of errs with equal and intolerable ignorance—and see if the one great unalterable difference in physiological life between a boy and a girl is even considered. It is not. And yet it is, it must be perforce, a potent factor in the whole question of girls' education."

The fact is that as yet we have not had sufficient experience in the direction of girls' education to come definitely to final conclusions. Speaking comparatively, it is a new movement, and such warnings as those just quoted, useful though they are as hints that caution and a reconsideration of the special needs of girls are necessary, should not lead to violent changes which are likely to do more harm than good. Though many questions raised are as yet insoluble, one thing at least seems tolerably clear, and that is the desirability of the introduction into all schools for girls of instruction in the scientific method. The inculcation of habits of exact observation, of accurate measurement, and of the absolute necessity for deriving all conclusions from sufficient premises, habits which are most easily and satisfactorily formed by the study of suitable branches of science, will act as the most effective corrective to the feminine disposition to arrive at conclusions intuitively, and to assert that a thing is so because it is so.

It may be pointed out here that there seems, judging

from the statistics of popular examinations, a disposition, in selecting the branch of science which shall form the foundation of the scientific instruction in girls' schools, to be guided rather by æsthetic than by educational considerations. To take one instance, in the local examinations of the University of Cambridge in 1902, while in the preliminary grade 1776 boys presented themselves in various branches of physics and chemistry, there were only 175 girls offering these subjects; on the contrary, 481 girls offered botany as compared with 65 boys. The same thing was true in the junior and senior grades; in the former about 5000 boys took up various subjects of physics and chemistry as compared with 300 girls, and in the latter the numbers were:—boys, more than 1300, girls, just over 100; in botany, on the contrary, the number of junior girls was 754, junior boys 29, of senior girls 261, senior boys 14. It is not suggested that it is impossible to inculcate scientific methods by means of the study of botany, for Prof. Miall has shown the contrary quite conclusively, but a knowledge of current text-books and methods leads to the belief that, nowadays at least, the above contention is a just one.

The urgent need at present, and one which might well engage the earnest attention of men of science, is to formulate a scheme of scientific instruction for girls' schools which, while inculcating the fundamental principles of physics and chemistry, shall lead to an intelligent application of these principles to the practical requirements of the household, whether in the kitchen, in the nursery, or in the general sanitary arrangements. Though such a course might well form the basis of the science teaching, there is no reason why an intelligent acquaintance with animate nature should not also be made. Nor need the special requirements of those girls who will later, instead of devoting their energies to home-life elect to take up scientific or medical work, be neglected. Since, as the imposing list of women engaged in scientific work given in the "Englishwoman's Year-Book," and the growing number of women doctors (177 were registered in the British Medical Register in 1894) show, there is an increasing attraction for women in the study of science, due provision for specialisation in science should be made in those secondary schools where girls remain until nineteen.

THE CONTINENT OF EUROPE.

In dealing with the provisions made for the university education of women in the different European countries, it is a little difficult to present inclusive generalisations. The local conditions vary so widely, and the national peculiarities are so various, that the most satisfactory plan is to deal separately with those countries in connection with which materials are available. Moreover, it is difficult within the limits of a single article, to attempt to summarise the history of the attempts made to improve matters so far as the higher education of women is concerned, and in the main it will be necessary to limit attention to the present state of affairs.

In Austria, to take the countries in alphabetical order, a decree of 1897, revising one made by the Minister of Education in 1878 regulating the admission of women to the universities of that country, ordained that any woman more than eighteen years of age who is a native of Austria may be admitted as a hearer to the philosophical faculty of an Austrian university, provided she has passed the *Reifeprüfung* or equivalent examination. The order for the admission of individual women is in the hands of the dean of the faculty, but an appeal may be made from his decision to the Minister of Education. Women hearers are under the same regulations as men. In 1896, Austrian women who had studied medicine at a foreign university were placed on the same footing as their countrymen in obtaining Austrian degrees in medicine. It is interesting to note in this connection that the first Austrian woman who obtained the degree of doctor of medicine did so at Vienna in 1897.

Women have been admitted to the universities of Belgium on the same conditions as men since 1883, though it must be stated that the Free University of Louvain is an exception, and does not admit women. Since 1890 an increasing number of Belgian women have availed themselves of the opportunity of university education.

To the Danish universities women have been admitted under the same conditions as men since 1875, and may take examinations and degrees in all faculties except that of theology, in which there is a special examination for women.

In Finland, women who wish to enter the University of Helsingfors, the only university in the country, must obtain the special permission of the chancellor of the university. Notwithstanding this impediment, there were in 1900 more than 200 women studying in the university.

All the courses in all the faculties and schools of the French universities with the exception of the *cours fermés* and the practical work are public, and open free of charge to persons of either sex as hearers. Matriculated students alone may attend practical work and the *cours fermés*; and to matriculate both men and women candidates must present a *diplôme de l'enseignement secondaire.* Women may become candidates for degrees on the same conditions as men. *Attestations d'études supérieures* are given by some faculties to hearers who have attended the courses regularly. In the provincial universities no requirement is made as to sex, but in Paris the hearer, to obtain the certificate, must have taken a bachelor's or an equivalent degree. It must be noted that not quite all the medical courses are open to women. The number of women students registered in French universities at the beginning of 1898 was 871, of whom 469 were studying medicine and 80 different branches of science. In the previous session 72 university degrees were obtained by women, but only one was in the science faculty, though 15 others were successful licentiates in science.

The universities of Germany do not treat women in a uniform manner. The conditions under which women study vary in different centres. As a rule, women are admitted only as hearers to the lectures of the philosophical faculty, though some German universities have permitted attendance in the legal and medical faculties. In the winter session of 1898–9, 414 women were in attendance at the ten Prussian universities as against 117 in 1895–6. At Berlin, Freiburg, Göttingen, Heidelberg, and Tübingen, women have been granted the degree of doctor of philosophy (Ph.D.). Even when women are admitted to the philosophical faculty of the universities they are mostly there on sufferance; they have no rights, and do not count as students. As Dr. Isabel Maddison has said, "the whole question of the admission of women to the universities has given rise to much discussion in Germany, and is still far from being settled. Many Germans regard the higher education of women as undesirable, and there is a strong objection manifested by a large number of the professors and students alike to the admission of women to the universities . . . the seriousness of purpose and the ability of individual women who have studied in Germany have, it is believed, done much towards destroying the prejudice against women students in the minds of the professors under whom they have worked."

In Greece, the National University in Athens was opened to women in 1895. The other institutions in the country of university standing, such as the English School of Archæology, admit women to their lectures. In 1895, too, the philosophical and medical departments of the universities of Hungary were opened to women by the Minister of Education, but to enter the universities they have to fulfil exactly the same conditions as men.

In Italy, in the Netherlands, and in Norway, women may enter the universities on a footing of equality with men. In Italy two classes of women students are admitted, viz. regular students and hearers. In the Netherlands no distinction is made between men and women; the latter are allowed to matriculate and to take degrees. Since 1884 women have been admitted to the lectures and degrees of the University of Christiania, and where there is no special regulation which prevents them, women may also compete for the scholarships and prizes.

All Russian universities exclude women. Special classes are held at St. Petersburg for the higher instruction of women under the supervision of the Minister of Public Instruction.

Speaking generally, the universities of Spain, Sweden, and Switzerland are open to women students. The Spanish universities have been open in a general way to women since 1857, when the universities of the country were placed under the control of the General Director of Public Education, but

Spanish women have made little use of the facilities offered. In Sweden, women appear to be excluded from the theological faculties, but since a Royal decree of 1870 they have been able to take medical degrees, and from 1873 the legal and philosophical faculties have been open to them. The seven universities of Switzerland are, without exception, open to women; the conditions under which they study vary somewhat in different universities.

AMERICA.

All courses and degrees of Canadian universities are, as a rule, open to women on the same terms as men, though in some cases they study for medical degrees in separate medical schools. The colleges of the various universities do not generally possess boarding accommodation for the students, who reside in boarding houses approved by the college authorities.

It is impossible at the end of a general article to do more than give one or two salient facts in reference to the higher education of the women of the United States. The report for 1899 of the Commissioner of Education states: "The barriers to women's higher education seem effectually removed, and to-day eight-tenths of the colleges, universities, and professional schools of the United States are open to women. . . . . The obtaining of a collegiate education gives the women more ambition to enter a profession, or if they decide to marry, it is stated that—'The advanced education they have received has added to their natural endowments, wisdom, strength, patience, balance, and self-control . . . and that in addition to a wise discharge of their domestic duties, their homes have become centres of scientific or literary study or of philanthropy in the communities in which they live.'"

The number of women undergraduate and resident graduate students in the colleges of university standing in the United States in the year 1900–1 was very nearly 47,000, and of these about 21,500 studied in colleges side by side with men. During this year 5050 degrees were conferred on women, nearly half as many as were gained by men, viz. 11,463.

Such are, in the barest outline, the leading facts as to the attitude of the more important countries towards the higher education of their women. The reader who desires more detailed knowledge should refer to the following sources of information, upon which the writer has largely based his conclusions:—"Handbook of British, Continental and Canadian Universities, with Special Mention of the Courses Open to Women," "Supplement to ditto, for 1897," by Dr. Isabel Maddison (New York: the Macmillan Co.). "Educational Systems of Great Britain and Ireland," by Graham Balfour (Oxford: Clarendon Press). "Education in the Nineteenth Century," edited by Dr. R. D. Roberts (Cambridge: University Press). "Growth of Educational Ideals during the 19th Century," by Sara A. Burstall (*The School World*, 1902). "Englishwoman's Year-Book, 1903" (Black). "Annual Reports of the Department of the Interior," by the Commissioner of Education (Washington: Government Printing Office).

A. T. SIMMONS.

CAVE EXPLORATION IN IRELAND.[1]

THERE is little doubt that the visit, a few years back, of the enthusiastic M. Martel, whose "Irlande et Cavernes anglaises" forms such pleasant reading, did much to rouse new interest in Irish caves. Dr. Forsyth Major soon after examined the Irish fossil Mammalia in the Dublin Museum of Science and Art, where Dr. Scharff was at the same time summarising his researches on the origins of the European fauna; on this question the pre-Glacial and post-Glacial Pleistocene remains naturally throw a considerable light. Mr. R. J. Ussher, already distinguished by his published work on southern caves, was fortunately again willing to devote his time to exploration. Circumstances were thus favourable to the formation of a committee, which, aided by grants from the Royal Irish Academy and the British Association, has examined certain caves near Ballymote, in the county of Sligo, and is actively engaged on others near Edenvale, in Clare.

[1] "The Exploration of the Caves of Kesh, County Sligo, being the First Report of the Committee, consisting of Dr. R. F. Scharff (chairman), George Coffey, Prof. Grenville A. J. Cole, R. J. Ussher, and R. Lloyd Praeger (secretary), appointed to Explore Irish Caves" (*Trans.* Royal Irish Academy, vol. xxxii. sect. B, part iv.). Pp. 46 and 3 plates. (Dublin, 1903). Price 2*s*.

The present report is a well edited quarto paper, with several illustrations. Mr. George Coffey, keeper of the collection of Irish antiquities in the Dublin Museum, deals with the traces of human occupation, and, like most of the contributors, has personal knowledge of the caves. The geological section is greatly strengthened by the visit of Mr. G. W. Lamplugh to Keshcorran, and his association as joint-author in the report. Messrs. A. S. Kennard and B. B. Woodward describe the Mollusca, and are known as specialists in this comparatively unworked branch. Mr. E. T. Newton, F.R.S., has identified the remains of birds, while Prof. D. J. Cunningham, F.R.S., describes the scanty human bones. In work where wide deductions may be founded on a single fragmentary relic, this specialisation among the contributors cannot be too highly praised.

Mr. Ussher's general description provides an interesting introduction to the detailed essays. Messrs. Cole and Lamplugh then show that the caves depend for their form on the joint-planes in the massive limestone, and that they were excavated by solution in pre-Glacial times. Glacial detritus then became banked against the slope, and crept into the caves from their mouths. As the ice melted, characteristic mounds of similar material were deposited in the lowland below Keshcorran.

A good part of the deposit within the caves is derived from the solution of the limestone, and includes characteristic bipyramidal crystals of quartz. A spicular crystalline material, mingled with the calcareous tufa, affecting polarised light, and soluble in acids, has unfortunately so far eluded determination. The possibility of the discovery of pre-Glacial remains in such caves in Ireland is pointed out.

As Mr. Ussher indicates, in commenting on Mr. Newton's list of the bones of birds from the caves, the smew, the grey plover, and the little auk are now rare inland, even in winter; the discovery of their remains has therefore some bearing on the climate during their occupation of Keshcorran. Dr. Scharff, in his account of the mammals, identifies the Arctic lemming, not previously known in Ireland. The remains of horse, obtained, with one exception, from the upper stratum of the principal cave that was examined, show that "horse-flesh probably formed one of the principal articles of diet of the cave-men." The traces of the mountain or Irish hare, the true *Lepus timidus* of Linné, indicate a larger animal than that now prevalent in Ireland. Bear (*Ursus arctos*) is represented by a fine left ramus of a lower jaw and very numerous remains. The distribution of the bones of all these animals is easily realised from the small maps provided, on which those found in the upper stratum are indicated separately from those in the lower.

Mr. George Coffey considers that man's occupation of the caves does not date back to a very remote period. Charcoal is frequent in the upper layers, and its distribution, together with the objects found, suggests a brief occupation of the caves in Neolithic times, and a more prolonged settlement when bronze and iron were both common. This latter occupation seems to have been as recent as the eighth to the eleventh century of our era, and Mr. Coffey ingeniously pictures the bear as responsible for the general avoidance of the locality in earlier times.

Mr. R. Lloyd Praeger, now editor to the Royal Irish Academy, summarises the results, and his detailed plan and the illustrative plates are worthy of the body which has undertaken their publication.

G. A. J. C.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

PROF. A. G. BOURNE, F.R.S., professor of biology at the Presidency College, is to take up the duties of Director of Public Instruction, Madras.

MR. H. J. MACKINDER, lecturer in economic geography at the London School of Economics, has been appointed director of the School in succession to Prof. W. A. S. Hewins, who has resigned the post.

ANNOUNCEMENT is made that Sir J. S. Burdon-Sanderson, F.R.S., regius professor of medicine at Oxford, has placed his resignation of the professorship in the hands of the vice-chancellor of the university.

THE Mysore Durbar has, says the *Pioneer Mail*, established four scholarships of 40 rupees a month each to encourage the study of analytical chemistry in the laboratory of the agricultural department. The scholarships will be tenable for one year, and will be open to candidates who have taken the B.A. degree in physical or any other branch of natural science. Students awarded scholarships will have to give an undertaking to serve the State for one year if required to do so, or to refund the money in case they refuse to serve.

IN a recent address at the distribution of prizes to the students of the classes held under the Liverpool School of Science subcommittee, Sir Philip Magnus, referring to the progress made in the provision of technical education in this country during the last few years, said that in 1886 the number of students in technological classes registered by the City Guilds Institute was 7060, and during the past session, that number has increased to 38,638. Moreover, apart from the sum of more than 1,000,000*l.* which local authorities expended last year on technical instruction as defined by the Technical Instruction Act, the State contributed the sum of 605,143*l.*, as against a total of 107,583*l.* in the year 1886, whilst the total State contribution last year to education generally amounted to more than 9,000,000*l.*, as against little more than 3,000,000*l.* in 1886.

AN appeal is being issued by the Senate of the University of London for funds to build and endow an institute of medical sciences under the control of the university. A letter signed by the chancellor of the university, Lord Rosebery, the vice-chancellor, principal and others has been circulated urging the claims of such an institute. Owing to the great changes which have taken place in medical education of late years, due to the increasing attention given to the teaching of the scientific subjects, it has become impossible, the letter states, for each medical school, out of the income derived from the fees of students, to build, equip, and maintain the laboratories, fitted with costly apparatus, which are necessary for modern scientific teaching. The faculty of medicine, a body consisting of 350 recognised teachers of the university, has ascertained the views of the teachers of the medical schools, and has recommended the Senate to establish an institute for the teaching of physics, chemistry, biology, anatomy, and physiology.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Astronomical Society, December 11.—Prof. H. H. Turner, F.R.S., president, in the chair.—Dr. A. A. **Rambaut** read a paper on two drawings of the Mare Serenitatis by John Russell, R.A., which afforded some hitherto unpublished evidence with regard to the appearance of Linné in 1788. Dr. Rambaut showed photographs of the original drawings, on which Linné appeared as a white spot, and not as a crater.—Mr. **Saunder** showed and described a photograph of one of the earliest maps of the moon, made by Langrenus about 1645.—The **Astronomer Royal** showed photographs of Comet Borrelly 1903 and Comet Perrine 1902, and pointed out their great similarity in appearance.—The Astronomer Royal also gave an account of the observations of the recent shower of Leonid meteors on the morning of November 16.—Mr. **Denning's** paper on the same subject was also read. There was complete agreement among the observers as to the maximum being between 17h. 30m. and 18h.—Mr. J. C. W. **Herschel** read a paper on an examination of the relative star density on different parts of the plates forming the Harvard photographic star map, from which it appeared that the maximum density was at about 9° from the centre of the plate, after which it fell off very rapidly.—Mr. **Crommelin** presented his ephemerides for physical observations of Saturn, 1903–4, and gave the different values that had been found for the planet's rotation period.—The secretary read a paper by Prof. G. W. **Hough** on the rotation period of Saturn deduced from his observations of the white spot first observed by Prof. Barnard on June 15.—Mr. Maunder read a letter from Mr. Percival **Lowell**, in which the latter affirmed his conviction of the reality of the canals of Mars, and also of the markings on Venus.—Prof. **Turner** described his graphical method for determining the local or Greenwich time of sunset at different places within a given region, and Mr. Benson spoke of a somewhat similar method previously devised by him.—The secretary read a paper by Mr. P. H. **Cowell** on the semidiameter, parallactic inequality, and variation of the moon derived from the Greenwich meridian observations from 1847·0 to 1901·5.—Mr. H. C. **Plummer** described and illustrated his paper on oscillating satellites.

Zoological Society, December 1.—Dr. Henry Woodward, F.R.S., vice-president, in the chair.—Prof. E. Ray **Lankester**, F.R.S., exhibited and made remarks upon some specimens of Medusæ reported to come from the Victoria Nyanza. Prof. Lankester also exhibited some drawings showing the hair-whorls on the face of two specimens of the okapi.—Mr. F. E. **Beddard**, F.R.S., exhibited and made remarks upon a portion of the large intestine and the cæcum of a boa (*Boa constrictor*) which had died in the Society's Gardens. The walls of the intestine in the neighbourhood of the cæcum and of the cæcum itself were thickened and inflamed. The cæcum was filled with a hard mass consisting of small stones and a number of the snake's own teeth, the presence of which, it was thought, had given rise to the inflammation.—Mr. Beddard also exhibited, on behalf of Mr. G. A. Doubleday, a hairless specimen of the common rat (*Mus decumanus*) which agreed in its characters with a so-called variety (*Mus nudo-plicatus*) of the common mouse figured in the Society's *Proceedings* (1856, p. 38, mamm. pl. xli.).—Dr. Walter **Kidd** exhibited a drawing of an *Oryx beisa* showing a reversed area of hair along the median line of the back, a character which was found only in ruminants, but not in all of them.—Mr. Oldfield **Thomas** exhibited an example of the naked rodent which he had in 1885 described as *Heterocephalus phillipsi*, but now thought should form a special genus, proposed to be called Fornamia, as its possession of only two cheek-teeth proved to be constant. The specimen had been presented to the British Museum by Dr. A. G. W. Bowen, R.N. A second species of Heterocephalus, distinguished by its smaller size and much smaller teeth, was described from British East Africa and named *H. ansorgei*.—Mr. G. A. **Boulenger**, F.R.S., exhibited a young hybrid newt (*Molge marmorata* ♂ × *M. cristata* ♀) obtained by Dr. Wolterstorff, of Magdeburg, in his aquarium, as reported in the *Zoologischer Anzeiger*, September 21. This specimen agrees in all external characters with *M. blasii*, de l'Isle, of which one of the original specimens, from near Nantes, S. Brittany, forming part of M. Lataste's collection, was also exhibited.—Mr. F. E. **Beddard**, F.R.S., read a paper on the tongue and windpipe of the American vultures, and remarked upon the inter-relations of the genera Sarcorhamphus, Gypagus, and Cathartes.—A communication from Miss Dorothy M. A. **Bate** contained an account of the species of mammals—fifteen in number—hitherto recorded from Cyprus. One subspecies—*Crocidura russula cypria*—was described as new to science.—The secretary, on behalf of Dr. R. N. **Salaman**, read a report on the *post-mortem* examination of the polar bear which had recently died in the Gardens. It stated that death was undoubtedly due to an aneurism of the aorta, which was possibly caused by a sharp bone at some previous time penetrating the œsophageal wall and lacerating the aortic wall.—A communication from Sir Charles **Eliot**, K.C.M.G., contained an account of thirty species of cryptobranchiate molluscs of the family Dorididæ from the east coast of Africa and Zanzibar. Of these eighteen were described as new.—A communication from Dr. A. G. **Butler** contained evidence in proof of the fact that the cardinal finch known as *Paroaria cervicalis* was only an immature condition of *P. capitata*.—Dr. P. Chalmers **Mitchell** read a paper on the occasional transformation of Meckel's diverticulum in birds into a gland.

Geological Society, December 2.—Sir Archibald Geikie, F.R.S., vice-president, in the chair.—Notes on the garnet-bearing and associated rocks of the Borrowdale volcanic series, by the late Mr. Edward E. **Walker.** A detailed description of sills and dykes of garnet-bearing rocks in the Langstrath Valley is given, and similar rocks are described, occurring as dykes and sills around the Eskdale granite and the Buttermere granophyre, and also in the Armboth-Helvellyn area. They consist of diabase, porphyrite, and granophyre. The rocks appear to be related to the Eskdale and Buttermere masses of intrusive rocks. Garnets are also found in a group of rocks below the great banded ashes and breccias of the Scawfell group, and in the rocks of the Scawfell group itself. These rocks often have a streaky structure, which exhibits types resulting from infiltration along planes of weakness, lamination of ash, flow of igneous material, and dynamic action on included fragments. The banded ashes of the Scawfell group also contain garnets. The garnets are of the almandine type. They often have a ring of felspar around them, which, when the intrusive rocks are studied, suggests that the mineral is original; but similar rings occur around garnets in the ashes, showing that the felspars may be formed in solid rock.—A contribution to the Glacial geology of Tasmania, by Prof. J. W. **Gregory,** F.R.S. After giving an analysis of previous contributions to this subject, the author describes the evidence obtained by himself personally in the northern portion of the island. The town of Gormanston stands on a Glacial moraine of recent geological age, formed later than the excavation of the Linda Valley, and occurring as a bank projecting from the southern side of the valley. The moraine is composed of typical Boulder-clay, and behind it are bedded clays, probably accumulated in a glacier lake above the moraine dam. An erratic of fossiliferous limestone, scratched all over and partly polished, is mentioned, while a railway has cut through an enormous boulder of black Carboniferous Limestone 16 feet in length. The northern face of Mt. Owen appears to be ice-worn to the height of about 1900 feet, while the base of the Glacial deposits is not more than 700 feet above the sea. The general evidence suggests that the Eldon Range and the central plateau formed the gathering-ground of the ice which flowed westward and south-westward. A map is given to show the range of Pleistocene glaciation so far as it has been recorded, and also to indicate localities of the glacial deposition, which probably dates from the Carboniferous period. The lowest level at which evidence of Pleistocene glaciation has been found is 400 feet on the Pieman River. Many of the deposits are little more altered than those of northern England, despite the heavy rainfall, and the aspect of some of the rock-scoring is very recent.

Entomological Society, December 2.—Prof. E. B. Poulton, F.R.S., president, in the chair.—Mr. G. T. Porritt exhibited, on behalf of Mr. T. Ashton **Lofthouse,** a specimen of *Xylophasia zollikoferi* taken at Sugar, near Middlesbrough, Yorkshire, on September 26 last. He said he believed that this was only the second specimen which had been recorded as having been taken in Britain. Mr. McLachlan, F.R.S., said the strongest evidence existed that a very large immigration of insects from the nearest Continental coast took place during the exceptional (for this year) spell of warm and calm weather prevailing towards the end of September, and he was of opinion that the specimen of *Xylophasia zollikoferi*, taken by Mr. Lofthouse in Yorkshire, formed an item in this migratory swarm. Mr. Eagle Clarke had witnessed such immigration when staying on board the "Kentish Knock" lightship for the purpose of studying bird-migration. He had witnessed a considerable immigration of *Vanessa cardui*, for instance, amongst many other insects, and not the least remarkable of his observations was the fact that *V. cardui* flies at night during migration as well as by day. Mr. McLachlan remarked that the laws governing migration in insects were at present little understood, and urged upon entomologists the necessity of obtaining a clearer insight into their working.—Mr. Malcolm **Burr** exhibited, and remarked on, a specimen of *Dinarchus dasypus*, Illig., belonging to a family of five or six species confined to the Balkans.—The president exhibited a series of photographs sent by Mr. A. H. **Thayer** to illustrate his views on the significance of the colours and patterns of butterflies' wings. The insects had been photographed on masses of foliage and flowers, and it was obvious that the dark ground-colour harmonised with the dark shadow behind and under the vegetation, while the light markings stood out as conventionalised representations of single flowers and flower-masses.—The president also exhibited the eyeless imagines and pupa-cases of *Ennomos autumnaria*, in illustration of his remarks at the meeting on November 18. Imagines produced by unblinded larvæ were also shown for comparison.—The Rev. Francis D. **Morice** read a paper entitled "Illustrations of the Male Terminal Segments and Armatures in Thirty-five Species of the Hymenopterous Genus Colletes."

Faraday Society, December 8.—Prof. A. K. Huntington presided.—The total and free energy of the lead accumulator, by Dr. **Lehfeldt.**—Bitumen in insulating compositions, part i., by Mr. J. A. **Sutherland.** Little or no trustworthy data have been published as to the use of bitumen for electrical purposes. The chief source of bitumen is Trinidad Lake, where there is estimated to be a quantity of nine million tons, which appears to be renewed to the extent of 20,000 tons annually. More than 150,000 tons are exported yearly. Bitumen is also found in Venezuela, California, and on the shores of the Dead Sea; it occurs in some limestone (asphalt) as an impregnation, about 10 to 15 per cent. being present, but it does not pay to extract it from this source. Its physical and chemical properties and constitution, which are fully dealt with in the paper, prove it to be infinitely superior to gas or coal tar for insulation and durability. The object of the present paper is to invite discussion and the views of electrical engineers to assist the author in the completion of his experiments, and to enable him to draw up a satisfactory definition of bitumen, so that users may secure the best results from its valuable non-hygroscopic and insulating qualities.

Royal Meteorological Society, December 16.—Capt. D. Wilson-Barker, president, in the chair.—Mr. W. **Marriott** gave some account of the meteorological work of the late Mr. James Glaisher, F.R.S. Mr. Glaisher was best known to the public for the twenty-eight balloon ascents which he made for scientific purposes in 1862–9 on behalf of the British Association committee. The highest ascent was that from Wolverhampton on September 5, 1862, when the height of about seven miles from the earth was reached. Mr. Glaisher was rendered insensible, while Mr. Coxwell's hands were frozen, and he was only able to open the valve of the balloon by tugging at the rope with his teeth.—A paper by Mr. J. R. **Sutton** on certain relationships between the diurnal curves of barometric pressure and vapour tension at Kenilworth (Kimberley), South Africa, in the absence of the author was read by the secretary.

PARIS.

Academy of Sciences, December 14.—M. Albert Gaudry in the chair.—The principal characters of band and line spectra, by M. H. **Deslandres.** The two classes of spectra have one important property in common, they are both formed by the repetition of similar groups of lines or bands, but there are numerous points of difference, the repetition of the groups being regulated by functions of different form in the two cases; line spectra are also affected by alteration of pressure and by an intense magnetic field, whilst band spectra are unaffected under similar conditions. The experiments made by the author, especially on the line and band spectra of nitrogen, are not in agreement with the usual view that line spectra correspond to the vibrations of the atoms, and band spectra to those of molecules. The views of Runge are also criticised, and the need of further experimental work pointed out.—Spectroscopical studies of the blood made on Mt. Blanc by the late M. Henocque, by M. J. **Janssen.**—The discovery of cones of Sequoia and of pine in the Portland strata in the neighbourhood of Boulogne-sur-Mer, by MM. R. **Zeiller** and P. **Fliche.**—On the suppression of magnetic hysteresis by an oscillating magnetic field, by M. P. **Duhem.** The author applies the theories previously developed by him to the experimental results of M. C. Maurain. M. Marconi has attributed the effects produced in his receiver to the suppression of magnetic viscosity, and M. Tissot to the suppression of

hysteresis; according to the author's theory it is the intervention of the viscosity which determines the suppression of the hysteresis.—The direct preparation of cyclohexanol and cyclohexanone starting from phenol, by MM. **Sabatier** and **Senderens**. The vapour of phenol mixed with hydrogen in excess and passed over reduced nickel at 215° to 230° C. gives a mixture of cyclohexanone and cyclohexanol. The vapour of this mixture, passed over reduced copper at 330° C., gives hexanone in a practically pure state; the same mixture, mixed with an excess of hydrogen and passed again over reduced nickel, gives the pure cyclohexanol. The method is general, and has been applied with success to the cresols.—On partial differential equations of the second order, by M. **Hadamard**.—On a generalisation of the theory of algebraical continued fractions, by M. E. **Goursat**.—On the differential equation of Riccati of the second order, by M. George **Wallenberg**.—A simple method permitting of the registration on the walls of a rotating cylinder of great pressures with small forces, by M. Albert **Hérisson**.—An internal combustion motor firing by compression, by M. **Cannevel**. In the motor described, the ignition is produced by a compression of about 30 atmospheres.—On a new method of measuring thicknesses and refractive indices, by MM. J. Macé **de Lépinay** and H. **Buisson**. The method consists in the observation of the rings of parallel plates and the fringes of mixed plates. The thickness of the plate is measured approximately to 0·01 mm., and the excess measured by the fringes, results having been obtained with plates up to 36 mm. thick. With plates of quartz of this thickness, the refractive index can be measured with an accuracy of some units in the seventh decimal place. Measurements on the same block of quartz, carried out on different portions of the plate, gave differences of four units in the sixth place, although the quartz was apparently perfectly homogeneous.—On the ionisation of phosphorus, by M. Eugène **Bloch**. Independent measurements of the mobilities, the coefficients of recombination, and of the ratio $\epsilon=\alpha/4\pi(K_1+K_2)$ for phosphorus ions lead to perfectly concordant results, the agreement giving the best demonstration of the real ionisation of phosphorus.—Study of a contact resistance, by M. A. **Blanc**. A contact resistance is of a very different nature from a metallic resistance, and is, under certain conditions, a reversible function of the intensity of the current. It undergoes an irreversible diminution whenever it is traversed by a sufficient current during an appreciable time, and this last phenomenon depends on the direction of the current.—On the distortion developed by shock in notched test-pieces, by M. A. **Pérot**. The effect of notching the test-piece is to limit to a narrow region the deformation produced, which is then recorded automatically by a photographic method. Diagrams are given showing the curves obtained with different specimens of the same metal.—Luminous sensation as a function of the time for coloured light. Discussion of the results, by MM. André **Broca** and D. **Sulzer**. A study of the retinal fatigue for different colours. Sources of light very rich in blue rays, such as the electric arc or very powerful incandescent burners, are injurious to the eye. The mean radiations of the spectrum, for which the energy is at a maximum, are those for which the human eye works most economically.—The emission of the n-rays (Blondlot rays) by the human organism, especially by the muscles and nerves, by M. Aug. **Charpentier** (see p. 182).—The action of a mixture of oxygen and hydrochloric acid on some metals, by M. Camille **Matignon**. Most of the metals of the platinum group are attacked by hydrochloric acid in the presence of air. Palladium and ruthenium are slowly attacked in the cold; iridium, rhodium and osmium at 150° C., the chloride being formed in all cases.—On the constitution and properties of the silicon steels, by M. Léon **Guillet**. Only steels containing less than 5 per cent. of silicon can be utilised; after tempering, these steels offer great resistance to shock, this power of resistance being relatively higher in high carbon steels. The results agree with those of M. Osmond in proving the existence of two solutions of silicon in iron, the one Fe—Si, the other $Fe—Fe_2Si$.—A new method for determining the critical points in iron and steel, by M. O. **Boudouard**. A modification of the self-recording method of Saladin, in which only one thermo-couple is required instead of two.—On meteoric irons, by MM. F. **Osmond** and G. **Cartaud**. Meteoric irons, on account of the extreme slowness of their cooling, show the normal state of equilibrium of the alloys of nickel and iron, whilst terrestrial alloys are in a metastable state.—On the preparation of the sesquiselenide of iridium, by MM. C. **Chabrié** and A. **Bouchonnet**. The selenide was prepared by the action of a stream of hydrogen selenide upon a solution of an iridium salt. It is amorphous, insoluble in nitric acid, and gave figures on analysis corresponding to Ir_2Se_3.—On the acetates of the alkaline earths, by M. Albert **Colson**. No acetochloride of calcium or magnesium, corresponding to the known barium salt, could be isolated.—The action of bromosuccinic and dibromosuccinic acids upon the pyridine and quinoline bases, by M. Louis **Dubreuil**. The action varies with the base and the solvent; by varying the experimental conditions malic, fumaric, bromofumaric, bromomaleic, and acetylenedicarboxylic acids can be isolated.—On a new tri-iodophenol, by M. P. **Brenans**.—Stereoisomerism in the esters of substituted camphocarbonic and methylhomocamphoric acids. Ethylcamphocarbonic acid, by M. J. **Minguin**.—Mercurammonium iodides of the primary and tertiary amines, by M. Maurice **François**.—On the esterification of phosphoric acid by glycerol, by M. P. **Carré**.—The origin of pearls, by M. Louis **Boutan**.—On the elementary factors of heredity, by M. Georges **Coutagne**.—On the geology and subterranean hydrology of the Eastern Caucasus, by MM. A. **Yermeloff** and E. A. **Martel**.—The supposed alcoholic fermentation of animal tissues, by M. F. **Batelli**. The results of the experiments described confirm those of Cohnheim, the alcoholic fermentation of the sugar obtained *in vitro* by extracts of the organs of higher animals being due to the presence of micro-organisms, and not to the action of an enzyme or of a nucleoproteid of animal origin.—Contribution to the study of amylo-coagulase, by M. A. **Boidin**.—Functional correlations between the poison glands and ovary in the common toad, by M. C. **Phisalix**.—The conditions special to the circulation of the glands in activity, by MM. G. **Moussu** and J. **Tissot**.

SIR H. JOHNSTON'S BRITISH MAMMALS.

British Mammals; an Attempt to Describe and Illustrate the Mammalian Fauna of the British Islands from the Commencement of the Pleistocene Period to the Present Day. By Sir H. Johnston. Woburn Library. Pp. xvi+405; illustrated. (London: Hutchinson and Co., 1903.) Price 12s. 6d.

UNLIKE the birds, the mammals of our islands have not been "written out," and there was accordingly abundant room for a thoroughly up-to-date and trustworthy work on this section of the British fauna, which should record all that has been accomplished in connection with the subject during the last ten years or so, and especially with regard to local races, or subspecies, of well-known types. Whether the author has been successful in satisfactorily filling the gap that lay before him it is our purpose to inquire.

In the first place, it may be candidly admitted that in this handsome and strikingly illustrated addition to the "Woburn Library" the author has succeeded in producing an extremely interesting and attractive volume, as, indeed, from his well-known literary skill and experience it might have been confidently predicted that he would do. The selection of a writer of the type of Sir H. Johnston to undertake such an important and difficult task reflects, however, to a certain extent on the methods and ways of professed naturalists. Had one of the latter class been entrusted with the work, it is only too likely that he would have produced a volume of the dry-as-dust style, wanting in literary skill and picturesqueness, and therefore practically unreadable by the general public. All such danger has been avoided by the selection of such a famous amateur as Sir H. Johnston, whose work is in many respects well suited to the needs of a popular *clientèle*, although we think there is somewhat too much of such "blessed words" as "alisphenoid canals," "entepicondylar foramina," &c., the significance of which will scarcely be appreciated by the class of readers the author is likely to attract.

As regards the general character and scope of his work, Sir Harry Johnston has made British mammals a peg on which to hang a long and somewhat discursive account of mammals in general, and extinct ones in particular, and it must be confessed that on many occasions he gets decidedly far away from his proper subject. In this connection it may be noticed that, although Sir Harry alludes to his work as a compilation, from the absence of references to authorities (which is a conspicuous feature throughout the volume) it might easily be imagined by the uninitiated reader that many of the theories (often alluded to as though they were facts) were the author's own, a case in point being the presumed African origin of certain elements in the South American fauna.

For our own part, we confess that we do not like the plan of mixing up the later extinct forms with those still living, as it tends to confusion and to give an exaggerated idea of the extent of the British fauna, which is now essentially of an island type. This, however, is purely a matter of opinion, and the author has a perfect right to follow his own inclinations in this respect. Even here, however, he makes a serious blunder at starting. For in the table of "epochs," on p. 16, he includes the Pleistocene in the "Tertiary" instead of in the "Quaternary."

Although confessedly an amateur, and to a great extent, therefore, unacquainted with the *technique* and details of his subject, Sir H. Johnston has apparently such overweening confidence in his own abilities and knowledge that he has scorned specialist aid in the revision of his proofs, which are consequently disfigured by a host of blunders and omissions. That the study of British mammals has not been advanced by his labours is a mild way of putting the matter. It might be urged, indeed, that in a popular work this was not to be expected, and were it not for the ambitious and comprehensive style in which the task has been attempted, there might be some justification for this plea. As it is, there is none.

To justify this indictment, we proceed to quote a selection from the errors and omissions.

Firstly, as regards mammals in general, we notice on p. 19 that Platanistid dolphins are stated to occur only in the Amazon and Ganges. On p. 48 a vague theory of the use of the folds in the throat of the rorquals is alluded to in a foot-note, but no reference at all is made to the main use of these structures, namely, to form a dilatable pouch for the temporary reception of prey. On p. 84 we find the term *calcaneum* employed instead of *calcar* for the supporting style in a bat's flying membrane. Three pages earlier (p. 81) we find it confidently stated that bats never produce more than two young at a birth, whereas the occurrence of three or four in an American family was announced early in 1902 by Mr. Thomas, and later on in the same year by Mr. Lyon. On p. 135 the astounding suggestion is made that the British fossil panda (*Ælurus anglicus*) may have been more nearly allied to *Æluropus* than to the members of the genus in which it is placed. Apparently the author has no conception of the differences between the molar teeth of the two genera. On p. 166 it is stated that hyænas have only one pair of lower premolars, while, on the next page, the lower carnassial tooth of the spotted hyæna is said to be "reduced in size" as compared with that of the striped species, whereas precisely the reverse of this is the case. These are not all the instances of the author's lack of knowledge concerning mammalian dentition, for on p. 115 we find no reference to the opinion that the functional dentition of marsupials represents the milk series, or to a paper published a few years ago in the Zoological Society's *Proceedings* in which it was attempted to show that the number of premolars in the same group is four instead of three. We should also much like to know what authority there is for the statement (p. 353) that the Indian nilgai is the nearest living ally of the oxen. Even more astonishing is the assertion, on the next page, that the bisons take their origin from the Oriental bibovine group of cattle, as represented by the gaur and banting. Apparently the author is un-

acquainted with the fact that the conformation of the skull and the position of the horns are quite enough to refute this, apart from the circumstance that the "bibovines" exhibit a specialised, and the bisons the primitive, type of coloration. Again, on p. 351, we are told that the ewes of the European mûflon are invariably hornless.

Many remarks might be made with regard to the author's knowledge of extinct mammals, but perhaps it will suffice to indicate the extent of this by reference to a passage on p. 270, where we are calmly told that the Pliocene brachydont *Rhinoceros etruscus* is identical with the Pleistocene hypsodont *R. leptorhinus*! If this be not enough, we may refer to p. 291, where it is suggested that the extinct Sedgwick's deer may be allied to the Oriental rusine group. Evidently the author does not know the difference between a "brow-tined" and a "fork-tined" antler, as, indeed, may be gathered from certain statements in regard to supposed roe-antlers later on in the work.

Passing on to the modern British fauna, a few lines may be devoted, in the first place, to the author's nomenclature. We are glad to see that, in the case of the generic names of the bats, modern usage is followed. We also note that in this group the author follows the "*Scomber-scomber*" usage, thus calling one species *Myotis myotis*. This being so, we fail to see why the otter and the badger are not respectively termed *Lutra lutra* and *Meles meles*, in place of *Lutra vulgaris* and *Meles taxus*. It is well to be consistent even in nomenclature! Still more surprised are we to find the weasel designated *Putorius vulgaris* on p. 161 and *P. nivalis* in the illustration on p. 163.

In the notice of Bechstein's bat, the author states that Mr. Millais took a specimen in 1902, whereas he should have written 1901, and he seems unaware that in the former year a note was published in regard to a specimen taken in 1886. In treating of the smaller rodents, the author has totally ignored the work of modern specialists. For instance, in the case of the squirrel, there is no mention of the fact that the British animal is regarded by specialists as a distinct form, which should be known as *Sciurus leucurus* if ranked as a species, or as *S. vulgaris leucurus* if a subspecies. Again, although mention is made of its seasonal colour-changes, the important fact that there is a curious difference in regard to the shedding of the coat on the body and on the tail is left unrecorded. Full reference should have been made to the paper by Mr. Thomas on this subject. Worse remains to be told in the case of the mice. In describing the wood-mouse, the author records and names five local races. Evidently, therefore, he considers such races worthy of notice. On turning, however, to the common mouse, we find no mention of the Hebridean wild form described by Captain Barrett-Hamilton as *Mus muralis* in 1899, while there is an equal lack of reference to the local forms of the harvest-mouse named by the same writer in that and the following year, and consequently the omission of the full title of the British race, namely *M. minutus minimus*. Neither is there any reference to the fact that the British short-tailed field-vole should be known as *M. agrestis neglectus*, as pointed out by Captain Hamilton in 1896. Bearing in mind what has been said with regard to the local races of the wood-mouse, we can only attribute these omissions to ignorance on the part of the author—ignorance for which there is not the faintest shadow of an excuse in these days of up-to-date Zoological Records.

Other instances of this type might be quoted. We pass on to notice, however, that on p. 296 the author has actually reproduced figures of certain antlers from Scotland, published by Mr. Millais as those of the roebuck, although it has long since been shown that the specimens in question are antlers of the South American pampas-deer which by some means had got into Scotland. Not content with this, Sir Harry proceeds to argue that these "fork-tined" antlers approximate to the red deer type. Evidently his lack of knowledge of antlers is on a par with that shown in connection with zoological literature.

After so much fault-finding, we are glad to record that the author calls the ancient wild ox by its proper name of aurochs, although, here again, if he would but take the trouble to read the descriptive label in the Natural History Museum he would find that his views as to the relationship of the white park cattle (which he will persist in calling wild) are far from being up to the level of those who know anything about the subject, and are acquainted with the meaning of albinism.

Among the most attractive features of the work are the coloured plates, all of which have been reproduced from original water-colour sketches by the author himself, whose artistic taste and powers are well known. Unlike the pictures of animals which we are accustomed to see in zoological publications, these sketches are designed from a decidedly artistic standpoint, and are admirably suited to a work of this nature. Many of the illustrations in black and white are also by the author, and are, for the most part, both life-like and artistic. We should, however, like to know what authority there is for depicting the long-eared bat (p. 105) with the ears depressed, while the wings are extended.

In conclusion, we may say that, had the author contented himself with writing a book of a less pretentious style, and ignored anatomy and subspecies, we should have had less cause to find fault with his effort. As it is, a thoroughly accurate, complete, and up-to-date book on British mammals has yet to be written.

R. L.

THERMODYNAMICS.

Treatise on Thermodynamics. By Dr. Max Planck. Translated by Alexander Ogg, M.A. Pp. xii+272. (London: Longmans, Green and Co., 1903.) Price 7s. 6d. net.

THE important part played by thermodynamics in modern physics, and especially in chemistry, is a sure guarantee that an English translation of Prof. Planck's work will receive a warm welcome in this country. It deals with the first and second laws, changes of state, systems defined by any number of

variables, the phase law, gaseous systems, dissociation, and dilute solutions.

As is well known to specialists in thermodynamics, Prof. Planck, instead of using the thermodynamic potentials of the majority of writers, prefers to deduce the conditions of equilibrium from the study of the function

$$\frac{(\text{energy}) - (\text{temp.})(\text{entropy}) + (\text{pressure})(\text{vol.})}{-(\text{temperature})},$$

i.e. the ordinary thermodynamic potential corresponding to temperature and pressure as independent variables, divided by temperature and reversed in sign. While this function has not the advantage of being an exact analogue of the potential functions in statics, the differential coefficients of which with respect to the position-coordinates are equal to the corresponding generalised force-components, its introduction undoubtedly serves to bring the conditions of equilibrium and stability of thermodynamic systems into closer connection with the entropy properties. We should prefer to see the principle of degradation of energy instead of the entropy principle adopted as the basis of thermodynamics. This would obviate the introduction of Planck's function, the ordinary thermodynamic potentials taking its place. The compensating drawback is that the available energy of a system is not a definite measurable quantity, but is dependent on the surrounding media.

The method of introducing such notions as temperature and entropy cannot be regarded as satisfactory. We find in chapter i. the usual juggling with the terms "perfect gas" and "absolute temperature." Thus absolute temperature is defined in § 9 by the expansion of gases, while in § 24 these gases are shown to obey laws which are not rigorously consistent with this definition of temperature. The term "perfect gas" is introduced in a vague sort of way in this chapter, but without sufficiently definite statements being made as to what is a perfect gas and what is not. To define absolute temperature by means of a perfect gas and then define a perfect gas by means of its laws of expansion referred to absolute temperature is merely working round in a circle.

Moreover, the *entropy* of unit mass of a substance is defined, in the first instance, by the formula

$$\phi = c_v \log \theta + R/m \log v + \text{const.},$$

applicable to the case of a perfect gas. This definition is suggestive of the definitions of *pole* and *polar* given in many text-books, according to which "the line $xx' + yy' = c^2$ is called the polar of the point $x'y'$ with respect to the circle $x^2 + y^2 = c^2$." But while the effects of the latter definitions are made patent by the absurd answers sent up by a large proportion of examination candidates to pole and polar questions on (*e.g.*) a so-called "general conic," opportunities at present do not occur so frequently in this country of testing how an average student, after reading such a treatment, would "define entropy." To define a physical quantity in the first instance by means of its value in a particular case, when the definition is not valid in the more general case, is certain to be misleading, and no amount of subsequent discussion, such as Prof. Planck admittedly gives, can set matters right. We have marked instances of the same thing in the old-fashioned treatment of electrostatics and magnetism, in which bodies were stated without reservation to attract one another according to the law of the inverse square, and when dielectrics were subsequently introduced there seemed something wrong about the whole theory which the writer of this review never cleared up until after his undergraduate days.

From this it will be seen that if Prof. Planck's treatise is no worse than many others on the same subject, it is in some essential points no better. It is a book which will be read with great interest by the physicist, generally in conjunction with other books on the same subject, but it is scarcely the book for an engineer to refer to for information on the nature of "entropy." G. H. B.

GEOGRAPHY AS A SCIENCE.

The Teaching of Geography. By Prof. J. W. Gregory, D.Sc., F.R.S. (Melbourne and London: Whitcombe and Tombs, Ltd.)

The Austral Geographies. Classes ii., iii., iv., v. and vi. Same Author and Publishers.

PROF. J. W. GREGORY is taking an active part in the promotion of sound geographical instruction in the land of his adoption. In a lecture recently published he sets forth the scope of geography and the way in which it should be applied to education. In a series of school-books he shows practically how he would do this for Australian children.

For Prof. Gregory geography is not a science, but a branch of knowledge which may be taught scientifically—its subject-matter is "description drawn from observation; it is not a search for underlying principles, nor a discovery of ultimate causes." In applying this descriptive knowledge to education Prof. Gregory points out that descriptions must glide into explanations and awaken interests which cannot be satisfied without understanding this world of ours. The geographer must not hesitate to borrow from literature, history, or science that which will make his appeal to his pupil's imaginations most stimulating. Prof. Gregory's scheme, as developed in the "Austral Geographies," is to begin with a plan of table, school-room, school, &c., leading to a map, directions, seasons, clouds, rivers, land forms (in the first stage these are definitions), a brief description of Victoria, and a few lines about other Australian States and the continents. In each succeeding book some sections of physiography are discussed, and are followed by a description of (*a*) Australasia in Class iii., (*b*) the continents ending with Australia in Class iv., (*c*) the British Empire in Class v., (*d*) Europe, U.S.A., Japan, Pacific Archipelagoes, and world trade routes in Class vi. Both the physiographical and the geographical parts are so planned that each year more advanced conceptions, as well as greater details, are given. The books, in the hands of a good teacher who applies the hints given in Prof. Gregory's lecture, should yield useful results, and teach the pupil much about land forms and climate and descriptive topography.

The physiographical part is the better, but the limitations which Prof. Gregory applies to geography have hampered his treatment of the rest of the book. The land forms (a better term than earth forms) are accurately described, but although in his lecture he vigorously insists on "the fact of facts in geography is the circulation of water by its evaporation from the sea, its movement through the air, as invisible aqueous vapour, its concentration in clouds, and its fall as rain," he practically ignores climate in his descriptions of the different countries. He loses more than half the educational value through this neglect. Climate and configuration are equally indispensable fundamental factors in geography.

We agree with him when he protests against the idea that anthropology, zoology, botany, astronomy and geology are but branches of geography. This is not the geographer's point of view. The misconception is due to the confusion of the old South Kensington physiography—a useful introduction to elementary science, mainly physical, especially in its cosmical and terrestrial aspects—with geography. This physiography, as Prof. Gregory points out in his preface, gave a valuable training to many a teacher of geography, and helped to expel deep-rooted fallacies and misleading expressions which were (and to some extent still are) to be found in many geographical textbooks. We fear that Prof. Gregory believes that geography consists of two parts, a physiographical part which is scientific, and a topographical part which is purely descriptive.

We have no wish to undervalue the descriptive aspect of geography, but this does not involve a rejection of geography as a branch of science. Prof. Gregory, and those who think as he does, have not yet shaken off the effects of their own schoolboy experiences. They have not seen the world as composed of a number of very complex associations of rock, water, air, plant, and animal, including man, which may be classified generically and specifically as readily as the organisms which they contain. The aim of the geographer, like that of the botanist or zoologist, is not confined to observing and describing phenomena, but includes comparison, classification and interpretation. It is a science, a science of forms which have not hitherto been generally recognised as such, and the activities within and around them. The educational value of geography is as much in its scientific discipline as in its appeal to the imagination and sympathy. Prof Gregory's books fall short of the ideal in so far as he excludes scientific geography from his descriptive pages. He has not yet recognised these higher groupings of phenomena connected by a specific topography. We venture to think that the first part of the twentieth century will be as noted for the recognition and study of these macro-organisms as the latter part of the nineteenth century was for the recognition and study of micro-organisms, and we believe that the beneficial effect on the body politic will be as great in the one case as it has been in the case of the individual in the other.

A. J. Herbertson.

LIQUID FUEL.

Liquid Fuel and its Combustion. By W. H. Booth. Pp. xx+411. (Westminster: Archibald Constable and Co., Ltd., 1903.) Price 24s. net.

In view of the great interest taken at the present time in the subject of liquid fuel and the part it is likely to play in the future, Mr. Booth's book comes as a welcome record of the work done in the past, and would have been enormously enhanced in value had the references to the original papers been fully quoted.

The first part of the work deals with the general properties and advantages of liquid fuel, and a good deal of this portion of the book might with advantage be omitted in a future edition, as, for instance, the chapter on water, its properties and purification, which are certainly out of place in a book devoted to a special subject and not likely to be used as a manual for boiler practice.

Mr. Booth's ideas on the subject of combustion are open to criticism, as he is evidently a strong believer in the preferential combustion of the hydrogen in hydrocarbons being the cause of the liberation of carbon in the form of smoke and soot when there is insufficient air for complete combustion in the boiler furnace, but a consideration of the actions taking place in a water gas generator may shake his belief in this, as, if at such temperatures any preferential action exists, the fact that steam passed through red-hot carbon yields carbon monoxide, carbon dioxide, and hydrogen would certainly point to carbon and not hydrogen as the element most favoured by the attentions of the oxygen at the temperature of the furnace.

On p. 105 the author breaks into amusing diatribes against the man of science, and comes to the conclusion that "when the most important industrial operations are absolutely neglected by our supposed teachers and leaders of scientific practice, it devolves upon those to whom science is less familiar, but more attractive, to step into the breach." This sentence probably explains a good deal of the vagueness to be found in the author's speculations on liquid and gaseous carbon and solid hydrogen in the portion of the work devoted to calorific value and combustion.

In the second part of the book practical engineering questions are dealt with, such as oil storage, the atomising of oil for combustion, and the work which has been done with liquid fuel, both on the Continent and in America, and here the author is thoroughly at home.

The engineering side of the question is admirably handled, and the collection of data which is given will render this part of the work of exceptional value to those dealing with this important subject.

The chapters on compressed air, flue gas analysis, and calorimeters will be welcome to many practical men, and the appendix is of special value as containing a report of the United States Naval Bureau on tests of liquid fuel for naval purposes.

There is no question that the time has now been reached when the methods of burning liquid fuel are

sufficiently advanced to ensure a very considerable advantage over solid fuel, and that the great point that remains to be solved is the oil supply, which at the present time is so completely in the hands of big commercial combinations that any development of its use at once leads to an increase in price that renders its employment impossible. It must also be clearly borne in mind that the total oil production of the world is but a small fraction of that which would be needed if liquid fuel became universally adopted, and that of this quantity only a small proportion would be of the quality fitted for fuel purposes on board ship.

Mr. Booth's book is one which will be welcomed by all interested in this very important subject.

OUR BOOK SHELF.

Die "Seele" als elementarer Naturfaktor. Studien über die Bewegungen der Organismen. By Hans Driesch. Pp. vi + 97. (Leipzig: Wilhelm Engelmann; London: Williams and Norgate, 1903.) Price 1s. 9*d*.

The relation of soul to body is sometimes formulated as a "parallelism," sometimes as "interaction," and difference of theory depends, as a rule, on differences of standpoint. There is, however, another point of view in some ways more promising; it deals primarily with the organism as a whole, and posits the problem, "How must we conceive organisms which present the phenomena of purposive action?" The position is promising, because it appears free from the presuppositions involved in the direct question, How is mind related to body? but it really has an equally ambiguous element, because it involves placing on one scale forms of life which cannot be shown to possess the required continuous gradation. None the less, the method is interesting, and this book is an interesting example of it.

First, the author argues that mechanical explanations of life are inadequate; they fail to account for complicated readjustments; they fail, above all, to account for reactions which are not simple reflex movements, but imply choice and trial of means. The criticism establishing this deals with the older theories of reflex action, instinct, and the "Zentrum." This "Zentrum," in any sense in which it subserves merely mechanical combination, must be rejected; for it the author has to substitute some conception which admits of "free combination." This conception suffers rather from brevity of exposition, and is defined chiefly by negation; some points emerge clearly; the physical elements (nervo-cerebral system) are not themselves final, but an intermediary factor; there is over and above these the system of what the author calls psychoids, apparently gradated (Oberpsychoid, Unterpsychoid, &c.); the structural basis of, *e.g.*, association does not contain in itself the regularity required, but is a means to it. In addition to the mechanical factors, autonomous factors are asserted; the "outer factors" condition, but do not make experience; the gap which a physicochemical theory leaves is filled by the "Psychoid-Theorie" (p. 66).

The author does not err on the side of dogmatism; his exposition is interesting, and its relations to cognate psychological and metaphysical doctrines are carefully indicated; but is there any proof that "Bioautonomie" has only this explanation? and is the solution by means of the "Psychoid" (supposing we know exactly what that is) more than an old problem in a new form?

G. S. B.

Indians of the South-west. By George A. Dorsey, Ph.D. (Chicago: Passenger Department, Atchison, Topeka and Santa Fe Railway System.)

It is characteristic of American enterprise that the Passenger Department of the Atchison, Topeka and Santa Fe Railway System should issue a concise handbook on the Indians of the south-west by a distinguished field anthropologist. This most fascinating and important ethnological area has been investigated by many distinguished American ethnologists, whose results have appeared in various publications. The disjointed character of these memoirs, although they are often presented with a great thoroughness, has rendered it difficult for students, on this side of the Atlantic at least, to gain a clear conception of the various Indian groups, and of the significance of their complex rituals. The time is therefore ripe for a succinct presentation of the main facts already published concerning these peoples. Dr. G. A. Dorsey, of the Field Columbian Museum, Chicago, has travelled extensively in the south-west, and readers of Nature have frequently been informed of his valuable contributions to American ethnology. He is therefore eminently qualified to undertake the task, and in the 223 pages of this book he has condensed a vast amount of trustworthy information regarding the daily life, industries, and religious ceremonial of the natives.

The following subjects are dealt with:—the tribes, linguistic stocks and industries of the south-west peoples; the Pueblos of the Upper and Lower Rio Grande; the homes of the ancients; Zuñi and the seven cities of Cibola; domestic life of the Hopi; Flute, Antelope, Snake, and other ceremonies; ancient home of the Hopi; the Navaho, the Apache; tribes of the Yuman and Piman stock, and the tribes of south-eastern California. The book is illustrated with a profusion of beautiful and instructive illustrations, and a valuable bibliography is appended. Doubtless the publication of this book, of which 15,000 copies have been issued, will lead to the south-west becoming a popular resort for tourists.

This will rapidly hasten the Europeanising and vulgarising of the most picturesque and unspoilt of the existing pagan peoples of North America; indeed, traces of this decay are not already wanting. If this book succeeds in the purpose for which it was brought out, it will materially, though unintentionally, help to destroy the last surviving relic of advanced pre-Columbian culture in North America.

The Butterflies and Moths of Europe. By W. F. Kirby, F.L.S., &c. Pp. lii + 432. (London: Cassell and Co., Ltd., 1903.) Price 21*s*. net.

This book was originally published in 1882, and then comprised all the species that were included in the catalogue of Staudinger and Wocke (1871). The present volume brings the subject much more up to present knowledge, as it now contains descriptions of all the species of strictly European butterflies and larger moths enumerated in the great catalogue of Palæarctic Lepidoptera published by Staudinger and Rebel in 1901. The few species found in Madeira and the Canary Islands, but not met with on the Continent of Europe, have also been included, so that the work will afford an excellent help to any entomological Continental tourist, or those who perforce escape the rigour of our winter months in the Atlantic islands. Mr. Kirby has also brought our knowledge of the larvæ of these species up to date by the description of those discovered since the publication of his previous volume.

The author has achieved considerable success in the difficult task of writing a popular guide without pro-

ducing a non-scientific volume, which is embellished with fifty-four plates, fifty-three of which are coloured, and contains a full and useful introduction. With this, among the many other popular works on natural history recently published, we may look forward to a prospective time, when the general reading public, and lovers of animal life, will be sufficiently acquainted with the main aspects of general zoology as to enable them better to grasp the real import of the many conclusions and theories—philosophical and otherwise—which have followed the great Darwinian conception. It may also be hoped that the narrative of life-histories of insects, now so frequently detailed and so easily consulted, may incite a further cultivation of economic entomology, a subject in which our American cousins still hold the field.

Grandeurs Géométriques. By J. Pionchon. Pp. 128. (Paris: Gauthier-Villars, 1903.) Price 3.50 francs.

EXPERIENCE in the teaching of young engineers at Grenoble has induced Prof. Pionchon to undertake the task of publishing some seventy little volumes presenting in a clear outline the fundamental notions, theoretical and practical, which should form the basis for further study. The collection includes sections on mathematics, mechanics, physics, electricity, and economics, and the present volume is the fourth of the first section. It explains in an elementary way the nature of the different geometrical entities and the methods by which they are measured. There is no attempt to dip beneath the surface and introduce any of the philosophy of the subject, but some passages in smaller print give rather more advanced considerations and analytical formulæ without proof.

If the book stood alone it could perhaps be passed without comment, but the prospect of seventy others of the same kind compels a word of criticism. It must be admitted that the contents appear to be perfectly sound, but beyond this we have little praise to bestow. Whatever it contains of value ought to be in the notebook of every engineering student who has had the minimum necessary instruction in mathematics, and if it is not already there, the reading of this volume will only lead to that undesirable sort of knowledge which too often forms the main part of the mathematical equipment of engineers, and is unfortunately encouraged by some of their teachers. The appearance of the pages suggests that they are designed to compensate physical as well as intellectual myopia, and this emphasises the inanity of many of the propositions. The author must be singularly devoid of the sense of humour. R. W. H. T. H.

LETTERS TO THE EDITOR.

Secondary Radiation produced by Radium Rays.

I LATELY had occasion to produce some radium radiographs of two partially overlapping pennies contained in a paper envelope which was laid directly upon the photographic plate. A print from one of the results shows that the shadow of the upper coin is blurred and diminished where the rays pass through air from the edge of this coin to the plate, but that it is sharp and of the correct size where the rays pass to the plate through the lower coin. This seems to point to the production of a considerable secondary radiation by the rays in their passage through air. L. R. WILBERFORCE.

University of Liverpool, December 22.

An Interesting Yucca.

IT frequently happens that facts of much general interest are published in systematic monographs and other taxonomic works, and are in consequence overlooked by many of those to whom they would be most valuable. Turning over the pages of the revision of the Liliaceous group Yucceæ, published with superb illustrations in the 1902 report of the Missouri Botanical Garden, I came across some statements which seem to deserve wider circulation and comment. The whole of the work referred to, by Dr. Wm. Trelease, is exceptionally well worth reading on account of the extremely lucid presentation of the facts, but the statements which especially interested me are as follows:—

The subgenus Chænoyucca contains thirteen species, some of which have the style green while others have it white. *Yucca glauca* is the very common narrow-leaved green-styled species of Colorado and northern New Mexico, extending to South Dakota and central Kansas. The inflorescence is simple, or with an occasional branch. *Yucca constricta* is a white-styled species, very similar to *Y. glauca*, found from the Pecos River region of Texas to Seward County, Kansas, where it meets the range of *Y. glauca*. It has the inflorescence rather amply branched at the top. A few years ago Mr. James Gurney, head gardener of the Missouri Botanical Garden, "was struck with the variety of foliage and difference of vigour of growth" shown by the Yuccas of Seward County, Kansas, all being ostensibly *Y. glauca*. He collected a considerable number of these plants to show the differences, and they were transferred to the Missouri Garden, where some of them have bloomed. Among them was one which had practically the foliage of *Y. glauca*, but it produced "a rather ample long-pedunculate panicle of pure white flowers, with white styles," which began to expand at the end of the flowering period of *Y. glauca*. This specimen was by no means to be separated from *Y. constricta*. Other specimens exhibited the normal flowers of *Y. glauca*, and still others had flowers like those of *glauca*, but with a conspicuously branched inflorescence. This last form agrees with the long-lost *Yucca stricta* of Sims, but is placed by Dr. Trelease as a variety of *Y. glauca*. In addition to these differences in the flowers, the foliage varied in breadth and flexibility.

No suggestion is made by the author that the phenomena described are the result of hybridisation, but it is well known that Yuccas are frequently crossed in cultivation, and Dr. Trelease presents an extended discussion of Yucca hybridisation in another part of his paper. In the case of the Seward County plants, we have an unexpected and great mutability developing locally in an ordinarily stable species of wide distribution; and is it not suggestive, to say the least, that this should occur just where the ranges of *Y. glauca* and *Y. constricta* overlap, and that the so-called *stricta* should have more or less intermediate characters taken as a whole, while the features taken separately are nevertheless pure? May this not be a case conforming with the Mendelian laws? In any event, it seems well worth consideration, for the mutability has to be explained somehow or other, that is to say, there must be a reason for it.

Granting the supposed hybrid origin of *Y. stricta*, the case is curiously parallel to that of the perplexing woodpeckers of the genus Colaptes inhabiting the same region, which are intermediate between the eastern yellow-shafted and western red-shafted species.

The only other Yucca which could be involved in the above discussion is the green-styled *Yucca mollis* (*Y. angustifolia mollis*, Engelmann, 1873),[1] but this is not known to extend so far west as to meet the range of *Y. glauca*.

T. D. A. COCKERELL.

Colorado Springs, Colorado, U.S.A., December 13.

[1] Dr. Trelease names this *Y. arkansana*, "in deference to the prevalent American practice in nomenclature" whereby *mollis* is held untenable because of Carrière's prior *Y. gloriosa mollis*, applied to a garden form. A practice which permits a name proposed for a garden variety of a different species to stand in the way of an otherwise valid specific name should surely be condemned.

SOKOTRA.[1]

Although the island of Sokotra is often seen by passengers on the great ocean steamers which pass by the Sokotran Archipelago on their voyages to and from India, eastern Asia and Australia, the fauna had been very imperfectly investigated when, in 1898, a party was dispatched by the joint exertions of the British and Liverpool Museums for the purpose of collecting specimens of the animals, vertebrate and invertebrate. The botany of Sokotra itself had been previously studied by Prof. Bayley Balfour and by Dr. Schweinfurth in 1879–81, and some collections of the animals occurring had been made by them and by other visitors to the islands, but the zoology was still incompletely known.

The party of 1898 consisted of Dr. H. O. Forbes himself, Mr. W. R. Ogilvie Grant, of the British Museum, and a taxidermist. Native assistants and servants were engaged at Aden, and valuable aid was given by the Government of India, which supplied means of transport between Aden and the islands, and lent camp equipage for the use of the explorers.

The Sokotran Archipelago consists of (1) the large island of Sokotra, about eighty-five miles in length, lying 150 miles to the eastward of Cape Gardafui in Africa and about 230 miles S.E. of Ras Fartak in Arabia; (2) Abd-el-Kuri, a much smaller island, lying about half way between Sokotra and Cape Gardafui; and (3 and 4) two islets, Semha and Darsi or Darzi, known as the Brothers, between Abd-el-Kuri and Sokotra. The two larger islands are separated by a submarine valley, 100 fathoms deep, whilst a channel several hundreds of fathoms in depth intervenes between Abd-el-Kuri and Cape Gardafui, and the sea between the islands and the Arabian coast is still deeper.

Dr. Forbes's party landed and made collections on Abd-el-Kuri, and they spent about two months in the hilly region of eastern Sokotra, but were unable to visit the smaller islets. The expedition was much delayed, first by some trivial political difficulties with the Sultan of Sokotra, and secondly, and more seriously, by severe attacks of fever.

Simultaneously with Dr. Forbes's expedition, an Austrian scientific party which, under the direction of Count Lambert, was engaged in exploring the archæology, geology, and natural history of southern Arabia, visited the Sokotran Islands. This party was larger and better equipped than Dr. Forbes's modest expedition, it had a steam vessel, the *Gottfried*, at its disposal, and was able to visit the islet of Semha as well as Sokotra and Abd-el-Kuri. Amongst the members of the Austrian party were Prof. Müller, Dr. Kossmat the geologist, and Prof. Simony the naturalist. At a time when Dr. Forbes's party was suffering severely from fever, and had almost been brought to a standstill by illness, most valuable medical assistance was given to them by the Austrians.

The finely illustrated volume now published contains the results of the expedition, and owes its appearance to the Museums Committee of the Corporation of Liverpool, which has provided the funds, and authorised the publication of the work as a special bulletin of the Liverpool Museums. The book is edited by Dr. Forbes, and comprises a narrative of the journey from his pen, and descriptions by various naturalists of the different groups of animals, vertebrate and invertebrate, collected by the expedition. The list of authors is too long to quote in full, but it comprises, besides Dr. Forbes and Mr. Grant, several eminent zoologists, amongst whom are Mr. Boulenger, Mr. E. A. Smith, Mr. R. I. Pocock, Sir G. Hampson, and Mr. W. F. Kirby, of the British Museum staff, besides Colonel Godwin Austen, Mr.

Fig. 1.—Camp at Adho-Dimellus. (From "The Natural History of Sokotra.")

[1] "The Natural History of Sokotra and Abd-el-Kuri." Edited by Henry O. Forbes, LL.D., Director of the Liverpool Museums, &c. Pp. xlvii+598; 30 plates and numerous figures in the text. (Liverpool: The Free Public Museums; Hy. Young and Sons; London: R. H. Porter.)

McLachlan, Lord Walsingham, and several others. A complete list of the plants of Sokotra and Abd-el-Kuri, inclusive of important additions obtained by Dr. Forbes, is furnished by Prof. Bayley Balfour, whilst a note by Prof. J. W. Gregory on the geology is a reprint of a short paper published in the *Geological Magazine* for 1899. This paper, which was founded on a collection of rock specimens brought back by Dr. Forbes's expedition, is supplemented by an extract from a report by Prof. Bonney on a similar collection made by Prof. Bayley Balfour in 1880. It is very much to be regretted that a translation of some of Dr. Kossmat's published notes on the geology was not also added, for whilst, as might be expected in reports on rock specimens collected by naturalists who are not geologists, the notes now reprinted give a fair account of the crystalline and volcanic rocks of the Sokotran group, they afford a very imperfect idea of the sedimentary formations, although the latter occupy by far the greater portion of the islands. The massive Nummulitic, Alveolina, and Hippuritic limestones, of which the islands chiefly consist, and which are of much greater geological importance than the granitic formations underlying them, are only mentioned vaguely as Cretaceous and Eocene limestones. No notice naturally is taken of one curious discrepancy between the collected specimens and Dr. Kossmat's statements. Both Prof. Balfour's and Dr. Forbes's collections from Sokotra contained comparatively modern volcanic rocks resembling those of Aden, whilst Dr. Kossmat states that no such rocks occur in Sokotra. ("Jungvulcanische Bildungen fehlen auf Sokotra—ganz im gegensatze zur gegenüberliegenden Küste Arabiens—vollständing," Sitz. math. nat. Cl. K. Akad. Wiss. Wien, 1899, p. 77.) The absence of Prof. Gregory in Australia is probably the reason why a fuller account of the geology as now known is not supplied.

FIG. 2.—Dragon's-Blood Tree. (From "The Natural History of Sokotra.")

The work is well illustrated with coloured plates and figures in the text. Amongst the plates, the representations of the wild ass (introduced by man but now feral), of some of the birds (especially a new goatsucker, *Caprimulgus Jonesi*), and of the land mollusca, spiders and insects (butterflies, moths, microlepidoptera, wasps and bees, beetles, &c.), are good examples of chromolithography. The text figures of mollusca and beetles, each surrounded by a grey rectangular area in which the actual shell or insect does not always occupy the central position, though good representations, have a somewhat unpleasing effect. The few figures of plants are good, and especial attention may be directed to the remarkable Euphorbia discovered by Dr. Forbes in Abd-el-Kuri.

As is usually the case in books like that now before us, some curious illustrations of zoological nomenclature are conspicuous. For instance, Mr. Kirkaldy, to whom we are indebted for an account of the Rhynchota, has invented a generic name which he spells *Klinophilos*. Naturalists in general who follow the old rules of Latin orthography would have written *Clinophilus*, but orthographical heterodoxy is by no means the most extraordinary feature of the case, for the new name is given to a genus the type of which appears, according to the rules of Linnæus himself, to be also the type of the Linnæan genus Cimex.

Again, in the two sections dealing with the land mollusca, each of the two authors quotes a generic name, Achatinelloides, given, not by themselves, but by another writer. It is difficult to understand why so absurd a term as this, derived from a double Latin diminutive of dubious accuracy by the addition of a Greek adjectival termination, should be preserved instead of being simply ignored. Some explanation, too, might have been vouchsafed why the same families of mollusca are termed Pomatiidæ and Pupidæ by one author, Cyclostomidæ and Helicidæ by the other.

The discussion of the "distribution of land and water in the Indian Ocean as indicated by a study of the fauna and flora of the islands" is one of the subjects mentioned in the preface as having been left over for a future publication. It is to be regretted that a general summary of the results obtained, so as to afford an idea of the zoological relations between Sokotra and the neighbouring continents, has not been added to the present volume, and it must be hoped that Dr. Forbes, who has already contributed to our knowledge of the distribution of animal life in the islands of the Indian Ocean, will before long publish his views on the results of his investigation of the Sokotran fauna.

The principal features of Sokotran zoology are the following. There are, as already remarked, no indigenous mammals, no batrachians or freshwater fishes. Amongst sixty-seven species of birds recorded from Sokotra, eleven appear to be peculiar to the island, and of the twenty-two hirds from Abd-el-Kuri three are unknown elsewhere. Of twenty Sokotran land reptiles no less than fifteen are peculiar, and three genera out of thirteen; the number known from Abd-el-Kuri is only three, of which two are peculiar to the island, whilst one is rather widely dis-

tributed. The forty-eight species of land mollusca inhabiting Sokotra are all, so far as known, restricted to the island, and the same is the case with the nine species from Abd-el-Kuri, whilst it appears very doubtful whether the Cyclostomaceous genus Lithidion, common to the two islands, ranges beyond the Archipelago. In arachnids, myriopods and insects, a large proportion of the species are peculiar, though not always to the same extent. As regards the relationship of the fauna in general, several of the naturalists direct attention to the presence of Mediterranean types, and in the case of the characteristic arachnids, Mr. R. I. Pocock shows that Mediterranean and Ethiopian elements prevail. Zoologically the Sokotran islands may be placed in the great semi-desert region or subregion that extends from the Atlantic to the Indus, but there is a considerable admixture in the fauna of Ethiopian representatives.

Geologically the islands consist of the remains of a plateau composed of almost undisturbed Upper Cretaceous and Eocene strata, resting upon granitoid Archæan rocks which protrude through their sedimentary covering in places and form peaks. The most conspicuous of the sedimentary formations are Nummulitic and Alveolina limestones, and "Rudistenkalk" with Radiolites, as in many other parts of the ancient Mediterranean area. According to the British observers, volcanic rocks of the Aden series are intrusive in the limestones.

It is clear, and on this all are agreed, that the Sokotran islands, although separated from Somaliland and Arabia by sea several hundreds of fathoms in depth, were once a part of the continent, and probably were connected with both Asia and Africa, but it is equally clear that the peculiarity of the fauna indicates long isolation, probably since Pliocene, if not from Miocene times.

In conclusion, whilst it is easy to point out omissions, it is only justice to say that in the publication of the present volume a difficult undertaking has been brought to a successful conclusion, and that all concerned in the production of the work deserve congratulation for having contributed so important an addition to zoological science. The present volume is much more nearly complete than most works of its kind, and has been brought out with praiseworthy despatch.

Of the two accompanying illustrations taken from Dr. Forbes's narrative of the journey, one affords an idea of the characteristic scenery in the Archæan Sokotran hills, and the other is an example of the peculiar vegetation of the island. W. T. B.

THE FOOD AND DRUGS ACTS.[1]

THE consideration of the circumstances which occasioned the epidemic of arsenical poisoning in the latter part of 1900, arising from the consumption of beer brewed from materials which were subsequently proved to contain large quantities of arsenic, and of the facts which resulted from their inquiry into the conditions under which other articles of food are actually prepared on a manufacturing scale, has led the Commissioners to direct attention to the extremely limited official control possessed by local authorities who are charged with the administration of the Acts relating to public health and the sale of food over the operations of manufacturers. The Commissioners point out that the existing machinery of public health administration provides little, if any, system of official control over the proceedings of manufacturers of food or of food ingredients. An individual or a company may start the manufacture of some new composition of food, to be sold under a "fancy" name, but there is no obligation to satisfy the local or any other public authority that the composition or the ingredients are wholesome, or that the conditions of preparation preclude the possibility of contamination by deleterious substances. The sanitary authorities of certain districts have obtained powers, under local Acts, to supervise the conditions of manufacture of ice-cream, but the principle is of extremely limited application in effect, and, broadly speaking, the control which can be exercised becomes available only after the food is on sale to the public. But even then the power possessed by the local authority under the Sale of Food and Drugs Acts is extremely circumscribed. Section 3 of the 1875 Act was drawn with the object of preventing adulteration of food with substances injurious to health, but it is so worded that it is almost impossible to obtain convictions under it, and as a consequence local authorities seldom proceed under it. A notable illustration of the impotence of the section was seen in the cases of prosecutions against publicans for selling arsenicated beer, where the proceedings were almost invariably laid under Section 6. Most persons are agreed that arsenic is a deleterious substance, but it was much easier to convict the publican of selling beer to the prejudice of the purchaser which was not of the nature, substance, or quality demanded than of selling beer containing a poisonous ingredient, to wit, arsenic. The irony of the situation is accentuated by the fact that whereas the fines under Section 3 have some relation to the gravity of the offence, and are sufficiently large to be deterrent, under Section 6, which was aimed at an entirely different class, they may be, and frequently are, wholly trivial.

Another illustration of the inadequacy of the section is seen in the case of "preservatives" in food. A departmental committee appointed by the Local Government Board has reported that in its opinion certain "preservatives" are noxious and deleterious, and has recommended their prohibition in articles of food. The Local Government Board has, as yet, done nothing with the report, but various local authorities, finding their hands strengthened by the body of evidence which the committee accumulated, have been emboldened to take steps to check the widespread use of such substances as boracic acid and formalin in connection with milk, but their action is seldom, if ever, brought under the section which imposes a stringent penalty on any person "who mixes . . . any article of food with any ingredient or so as to render the article injurious to health with intent that the same may be sold in that state," but under the section which affords a chance of the magistrate saying that milk *plus* preservative contains more than the purchaser bargained for, and was therefore not of the nature, substance, and quality demanded.

The difficulty, of course, in Section 3 is to prove knowledge and "intent" on the part of the seller, but there is very little doubt that if convictions could be more readily gained under Section 3 the use of preservatives would receive a much needed check.

A public department may, however, be spurred into activity when its interests are jeopardised, and here again beer supplies us with a notable illustration. Beer, as we all know, furnishes much of the revenue of this country, and anything which affects the interests of beer may *pro tanto* be held to affect the

[1] See the article in last week's NATURE, p. 179. The papers referred to are (1) Final Report of the Royal Commission appointed to inquire into Arsenical Poisoning from the Consumption of Beer and other Articles of Food or Drink. (Parliamentary Paper. Cd. 1848. 1903.) (2) Final Report of the Departmental Committee appointed to inquire and report upon the desirability of Regulations under Section 4 of the Sale of Food and Drugs Act 1899 for Butter. (Parliamentary Paper. Cd. 1749. 1903.)

interests of the Revenue. Accordingly the Revenue authorities look pretty sharply after the brewers, and exercise considerable powers with regard to the ingredients which may be used by them. By the Customs and Revenue Act of 1888 the Commissioners of the Treasury have power to prohibit, by issue of an order published in the *London Gazette*, the use in the manufacture or preparation for sale of any article of excise, of any "substance or liquor of a noxious or detrimental nature," or which, "being a chemical or artificial extract or product, may affect prejudicially the interests of the Revenue," and it was in terms of this Act that the Commissioners of the Treasury, acting under the advice of the Commissioners of Inland Revenue, prohibited in 1901 the use of arsenicated glucose and "invert" sugar in the manufacture of beer under a penalty of 50*l*. To the plain man there is an element of humour—grim humour, it must be admitted—about this procedure. Apparently such is the condition of the Statute Book with respect to official control in the interests of public health of the manufacture of articles of food and drink that this is the only known administrative method of arresting a grave public danger—unless, indeed, the incriminated material is of such a character that it may be taken in transit, and that the whole of it may be brought before a magistrate in a police court by direction of a medical officer of health. The action of the Treasury is, it will be observed, restricted to articles of excise, and is exercised ostensibly solely in the interests of the Revenue. No action was, or apparently could be, taken by the local authority in the district in which the works of Bostock and Co. were situated to seize or otherwise deal with the large quantity of contaminated glucose, "invert" sugar, and table syrup stored at these works after their poisonous nature was discovered.

Apart from the injunctions they have laid upon the excise authorities to extend the application of the powers they already possess to ensure the purity of beer, the chief outcome of the Commissioners' protracted inquiry has been to formulate a series of recommendations, or rather propositions, as to the necessity for more extended administration by the Local Government Board; as to the necessity for official "standards" for purposes of the Sale of Food and Drugs Acts; as to the responsibility of the manufacturer or intermediate vendor—that is, apart from the retailer—under the Sale of Food and Drugs Acts; and as to the extension of the powers of local authorities to prevent the sale of suspected foods pending analysis.

With respect to the Local Government Board, the Commissioners are of opinion that this department ought to have the services of a special officer with scientific knowledge, who should be in relation with the Government Laboratory, and be able to institute the necessary chemical inquiries, and in other ways (for instance, where physiological investigations are necessary) have adequate assistance In this way the Commissioners think that full and authoritative investigation could be made where risks to health are suspected, or where new colouring matters, preservatives, or other chemical additions to food are introduced. The officer ought not only to have the duty of collecting information from public analysts and other local officers, and of advising how the Sale of Food and Drugs Acts may be efficiently worked, but he should be required to make inspections and inquiries as to conditions of food-manufacture at home and abroad. Under the improved condition thus contemplated, the Local Government Board should for such purposes be in touch with other public departments which might be able to render assistance in special directions, *e.g.* the Board of Inland Revenue in the case of excisable articles, the Board of Customs in the case of imported foods, and the Patent Office in the case of patented processes of food preparation.

The Commissioners are of opinion that the Local Government Board should be the authority to prescribe and from time to time vary "standards" for the purpose of the Sale of Food and Drugs Acts. By the Act of 1899 the Board of Agriculture has been empowered to make regulations, which may imply "standards," with respect to milk, cream, butter, or cheese, articles which—and especially the first-named—are more frequently the subject of prosecutions under the Acts than any other food substances. There is a slight difference of opinion as to the manner in which these "standards" should be arrived at. The majority of the Commissioners favour the establishment of a so-called Board of Reference, which they define to be a permanent body consisting of a small number of scientific men nominated by the Crown or departmentally. The principal of the Government Laboratory, who, apparently, does not dissent from the idea of a consultative board to advise on points connected with the Sale of Food and Drugs Acts, thinks that it would be preferable to follow the procedure of the Board of Agriculture and to entrust the consideration of the propriety of fixing a standard, or standards in the case of particular groups of allied substances, to specially constituted committees, appointed *ad hoc* and for the occasion, in which manufacturers and technical experts were represented. There is, no doubt, much to be said on both sides of this question, but considering the very large and legitimate commercial interests involved, it is questionable whether public opinion would be wholly satisfied by the exclusion from the board of persons of special knowledge and experience of the article for which a "standard" is required.

After all, the number of substances, or groups of allied substances, for which "standards" would be required is not inordinately large.

A matter of more immediate importance is the nature of the amendment which is required to bring home to the real offender the responsibility for a contravention of the Acts. At present the actual manufacturer of an adulterated article is too frequently allowed to escape, and owing to the difficulty of reaching him, local authorities are often unwilling to take action, on the ground that they do not regard the retailer, who has had nothing to do with the contamination and is frequently not in a position to know that it exists, as the really culpable person. Warranties are very difficult to take action upon, and the conditions which have to be complied with under the Statutes are so numerous and so exacting that it is well nigh hopeless to proceed. If a warrantor states that at the time of giving a warranty "he had reason to believe that the statements contained therein were true," he has a good defence. As the law stands at present it is rarely worth while to attach the manufacturer or middleman to the prosecution.

The particular method of arriving at a food-standard advocated by Dr. Thorpe is well exemplified by the second of the two Parliamentary papers under review. In July, 1901, the departments concerned appointed a committee to inquire and report as to what regulations, if any, may with advantage be made under Section 4 of the Sale of Food and Drugs Act 1899 for determining what deficiency in any of the normal constituents of butter, or what addition of extraneous matter or proportion of water in any sample of butter shall for the purposes of the Sale of Food and Drugs Acts raise

a presumption that the butter is not genuine. In its first report the committee, which was a large and representative one, consisting of analysts, producers, vendors, and public officials connected with the English and Irish Boards of Agriculture, under the chairmanship of Sir Horace Plunkett, after hearing evidence in this country and in Ireland, unanimously recommended the adoption of a limit of 16 per cent. for the proportion of water, and this recommendation was promptly given effect to in the Sale of Butter Regulations 1902.

In the present report the committee deals with the other matters referred to it. These questions have led it to inquire into the chemical nature of butter, to ascertain how far the composition of butter-fat is dependent upon conditions of production and within what limits it may vary. It has also had to inquire into the nature of the substances which may be used for the purpose of adulterating butter, and what methods are open to analysts to detect and determine the extent of such adulteration.

The space at our disposal precludes any attempt to deal in detail with the many interesting points connected with the chemical nature of butter which have come out in the course of the inquiry. Observation has shown that the chemical constitution of butter-fat is dependent to a certain extent upon climatic conditions, period of lactation, nature and amount of food, breed and idiosyncrasy of the cow. The extent to which its composition may vary from these several causes is shown in the evidence which was taken, and which is summarised in the report.

The majority—one member, a butter vendor, alone dissenting—were of opinion that for the purposes of the Sale of Food and Drugs Act 1899 it was expedient to recommend a limit or "standard" based on a deficiency in the normal constituents of butter, and that it was desirable that the limit should have regard to what all authorities are agreed are the characteristic constituents of butter-fat, namely, the volatile acids, which by general consent is by far the most important criterion in butter analysis. They recommend, therefore, that if the amount of the volatile acids in any sample of butter, as determined by the Reichert-Wollny method—a description of which is appended in a schedule to the report—should fall below the number 24, a presumption should be raised that the butter is not genuine. Two members of the committee are disposed to place the limit at 23.

The committee is strongly impressed with the necessity of taking such steps as would directly identify margarine if present in butter, and with this view it recommends that all margarine made or imported into this country should be "ear-marked," as is done in Germany, Austria, and Belgium, and as it is proposed should be done in France, by the addition of 10 per cent. of sesamé oil during its manufacture.

It further suggests that steps should be taken to give effect to the recommendations of the Dairy Congress held at Brussels on April 27 and 28, 1902, to secure international agreement on the subject of control of the manufacture of butter and margarine. In a large number of the countries producing butter for sale in this country a system of control more or less well organised and under State authority already exists, and there ought to be little difficulty in securing by international cooperation and agreement that the system should be uniform and effective.

It remains to be seen what the Minister of Agriculture will do with a report which is particularly interesting as a contribution to the literature of a subject of great importance to the community, and is evidently the carefully digested result of an exhaustive and complicated inquiry.

THE JANUARY METEORS.

THESE meteors shoot from a point at about 230° + 53° in Bode's modern constellation Quadrans Muralis, placed in the barren region between Boötes, Draco, and Hercules. But the former constellation has never been generally recognised and admitted into recent star-maps. The name "Boötids" has, in fact, been sometimes suggested as preferable to "Quadrantids" for this new-year meteor-shower.

In 1904 the meteors will probably return in their greatest abundance on the nights following January 3 and 4, but the moon will unfortunately be full, and only the brighter members of the shower will be visible. But watches of the sky should be maintained on the early evenings of January 3 and 4, and also on the mornings of those dates (between about 5 and 7 a.m.) if the weather is sufficiently clear. A few large meteors are sure to be visible, notwithstanding the strong moonlight. In some years, when all the conditions are favourable, the display of January meteors is as plentiful as that observed during an average Perseid shower. The really active period of the Quadrantids (or Boötids) is usually very brief, being confined to a few hours. Meteors in the front of the stream begin to appear on about December 28, and the display seems practically exhausted on January 5 or 6. The radiant has a very low northerly position during the greater part of the night, and the meteors exhibit long flights and moderately swift motions.

W. F. DENNING.

NOTES.

M. ALPHONSE ROBERT, the energetic natural history collector who accompanied Dr. Forsyth Major some years ago in his expedition to Madagascar, and who only returned to England a few months ago from a three years' sojourn in Brazil, has just started on another collecting trip to the latter country, where his first destination is Para. The expenses of both the previous and the present expedition, which are undertaken in the interests of the British Museum, are borne by Mrs. Percy Sladen. M. Robert, we understand, intends to spend some time collecting at Para, and thence to ascend the Amazons into Peruvian territory. The specimens collected by M. Robert during his last trip have done much to increase our knowledge of the mammalian fauna of the Matto Grosso and adjacent districts of Brazil, and the novelties obtained have been from time to time recorded by Mr. O. Thomas in the *Annals of Natural History*. Among these are several new bats (one indicating a new generic type), a squirrel, and a new race of the crab-eating fox (*Canis thous angulensis*). M. Robert has also obtained a fine series of skins of the large and handsome brown woolly spider-monkey (*Brachyteles arachnoides*), a pair of which are now being set up by Mr. Rowland Ward for the British (Natural History) Museum.

THE report submitted at the second annual meeting of the trustees of the Carnegie Institution, held in Washington recently, shows that sixty-six grants were made by the executive committee for scientific research, amounting to an aggregate sum of 30,000*l*., the recipients of which represent every part of the United States and the smaller colleges as well as the large universities, observatories and laboratories. Twenty-five research assistants were appointed. These sums are exclusive of administrative and incidental expenses of the Institution. Arrangements have been made for publication at an early day of eleven scientific papers,

most of them making large and costly volumes. Among the subjects now under consideration by the Institution in connection with grants are a solar observatory, southern observatory, geophysical laboratory, Transcaspian exploration and archæological exploration, exploration in the south Pacific, establishment of biological experiment laboratories and international magnetic researches. The trustees authorised an aggregate expenditure of 75,000*l.* in grants for scientific researches and 8000*l.* for publications during the ensuing year.

The large gold medal for services rendered to art and science has been awarded by the German Government to Prof. Ehrlich.

The French Minister of Public Instruction has been authorised, says *La Nature*, to prepare a Bill arranging for the creation of a chair of general physics in connection with the science faculty of the University of Paris. This chair is intended for M. Curie.

A Reuter message from Stockholm announces that Baron Erland Nordenskjöld's expedition to Peru and Bolivia will leave for Southampton on January 6. It will proceed thence to Panama, and will arrive about February 15 at La Paz, the capital of Bolivia, which will be the departing point for the expedition to Lake Titicaca.

The Brothers Kearton have arranged to hold an exhibition of enlarged photographs of birds, beasts, reptiles, and insects at the Modern Gallery, Bond Street, W., on January 2–12, 1904, inclusive. The Gallery will be open from 10 a.m. until 9 p.m., and Mr. R. Kearton will deliver limelight lectures to children each afternoon, and to adults in the evening.

The death on December 19 at Hove of Mr. John Henry Brown recalls the little-known fact that, as the inventor of the iris diaphragm, he has laid the scientific world under a considerable obligation. "In the early seventies," Dr. Hollis writes from Hove, "he took his home-made model to Smith and Beck, the predecessors of the well-known firm of opticians in Cornhill. This model he showed me, many years ago, and although roughly constructed it differed in no important detail from the type of apparatus at present in the market. As he did not patent the little contrivance he reaped no pecuniary reward for his ingenuity. Although frail in body and physically somewhat infirm, Mr. Brown by indomitable energy made and retained for many years a large practice as a dental surgeon. He was a fellow of the Royal Astronomical Society, and died aged sixty-seven much respected."

The President of the Board of Agriculture and Fisheries has appointed a departmental committee to inquire into and report upon the present position of fruit culture in Great Britain, and to consider whether any further measures might with advantage be taken for its promotion and encouragement. The committee is constituted as follows:—Mr. A. G. Boscawen, M.P., chairman, Mr. C. W. Radcliffe Cooke, Mr. J. M. Hodge, Colonel Charles W. Long, M.P., Mr. George Monro, Mr. P. Spencer Pickering, F.R.S., Dr. W. Somerville, an assistant secretary of the Board of Agriculture and Fisheries, Mr. Edwin Vinson, and Rev. W. Wilks, secretary of the Royal Horticultural Society. Mr. Ernest Garnsey, of the Board of Agriculture and Fisheries, will act as secretary to the committee.

At the meeting of the Institution of Civil Engineers on December 22, Dr. T. E. Stanton described experiments made in the engineering department of the National Physical Laboratory on the distribution and intensity of the pressure on thin plates and combinations of plates placed in a uniform current of air. The results show that, under the given experimental conditions, a definite relation existed and may be stated thus:—For similar and similarly situated plates or combinations of plates in a uniform current of air, the intensity of pressure is the same for the same velocity of current and general atmospheric conditions. On the assumption that the motion of the wind approximates to that of a uniform current, the distribution and intensity of the pressure of the wind on structures may be studied experimentally by means of models of the structures set up in a current of air produced by means of a fan. In illustration of this, the results of experiments made on models of roofs and lattice girders of simple form were given. Tabulated results are also given for the cases of parallel plates at varying distances apart, plates inclined at varying angles to the direction of the current, and rectangular plates of varying ratio of length to width.

Mr. R. G. Carruthers and Mr. G. W. Grabham have been appointed geologists on the Geological Survey of the United Kingdom.

Mr. L. M. Lambe has given a description of the lower jaw of Dryptosaurus obtained from the Cretaceous strata of north-western Canada (*Ottawa Naturalist*, xvii., November).

In our brief notice of Mr. R. B. Newton's article on fossils from Borneo (Nature, December 10, p. 139) it should have been distinctly stated that Trigonia was for the first time recorded from the Jurassic rocks of that island. The genus had previously been recorded from the Cretaceous strata of Borneo.

In the *Annals* of the South African Museum (vol. iv., part ii., November) there is a series of articles by Dr. R. Broom on fossil reptilian remains collected by officers of the Geological Survey of Cape Colony. He describes an almost perfect skeleton of *Pareiasaurus serridens*, some new theriodonts, including three new genera, also a new and primitive rhynchocephalian from the Karroo beds. This last reptile is named Proterosuchus, and it shows a considerable degree of specialisation along the line which gave rise to the early crocodiles and dinosaurs.

In the *Proceedings* of the Cotteswold Naturalists' Field Club (vol. xiv. part iii., November) there is an interesting historical and geographical article on the Cotteswold Hills by Mr. S. S. Buckman, who deals with the origin of the name and the area to which it should properly be restricted. Messrs. T. Pears and L. Richardson describe some alluvial deposits at Clifton Hampden, near Oxford, and Messrs. A. S. Kennard and B. B. Woodward contribute notes on the land and fresh-water Mollusca found in the deposits. Among the species it is interesting to note *Dreissensia polymorpha*, as the occurrence of this mollusc in Britain was first observed in 1824, when living examples were found in the Commercial Docks, and it was held that the species had been imported.

In the *American Journal of Science* (December) Mr. G. R. Wieland discusses Polar climate in reference to the evolution of plants and animals, expressing the view that the northern circumpolar area has probably been, ever since the older Palæozoic era, the main evolutionary centre from which animal and plant life have radiated. In the same journal Mr. J. C. Branner directs attention to the resemblance between the Peak of Fernando de Noronha and the intrusive plug or obelisk of Mont Pelée, in Martinique,

described by Dr. Hovey. He also quotes an interesting passage from Darwin's "Journal," in which the author remarked of the Fernando Peak that "at first one is inclined to believe that it has been suddenly pushed up in a semi-fluid state."

The veteran traveller, Baron F. von Richthofen, selected a geographical subject for his inaugural address as rector of the University of Berlin (*Zeitschrift der Gesellschaft für Erdkunde zu Berlin*, 1903, p. 655). In dealing with the motives and course of geographical inquiry in the nineteenth century, he includes a considerable review of the work of early explorers. Twenty pages, indeed, have passed before we come to the final fourteen in which his true subject is discussed. The personal aims and influence of the rector are thus somewhat modestly and rigidly suppressed, and the address assumes a strictly academic character. It is well pointed out that tales of fabulous gold have prompted a large part of exploration. Yet geographical discovery, from whatever motive, has ended in that widening of the field of view which forms the essential feature of human progress. The promoters of colonial enterprise, it is urged, commonly overlook this incalculable result of their endeavours. The author traces the rise of scientific geography from the stage of mere universal description, and points out how the culture of Germany has allotted its proper place in the university curriculum to a subject so intimately connected with the search after truth and the welfare of mankind.

In the *Physical Review* for October Mr. Edgar Buckingham gives a concise deduction of Stefan's law, according to which the total temperature radiation of a black body is proportional to the fourth power of the absolute temperature. This deduction, which is a modification of Boltzmann's, is based on the free energy principle, but the corresponding reciprocal thermodynamical relation can be used instead if preferred.

Dr. Marage publishes a series of observations on the artificial development and measurement of the sense of hearing in deaf mute subjects. A considerable number of cases were experimented on, a vowel-syren producing the sounds ou, o, a, é, i being adopted for the purpose, and curves were drawn showing the intensity of sound audible to the patients at different stages of the treatment, as measured by the air pressure necessary to render the sounds of the syren audible. The author maintains that there are but few subjects who are deaf and dumb beyond all cure, and that the use of the syren will often restore the power of hearing, even in cases of complete deafness, usually within about six weeks. The sounds, so far from being fatiguing or painful to the subjects, appear to give them genuine pleasure.

Prof. Giacomo Ciamician has published his inaugural address delivered in the University of Bologna on November 7, dealing with the problems of chemistry of the new century. After giving a general survey of recent advances in chemistry and physics, the author turns his attention to the problem of developing chemical industries in Italy. Already enormous strides have been made in the manufacture of iron and steel, of sulphuric acid (the production of which has increased fivefold in ten years), of sugar (in which the increase in five years has been from 50 to 800 thousand quintals), and of calcium carbide. Among the obstacles to further progress mentioned by the author are the action of the Government in checking the growth of new industries by excessive taxation, the timidity of capitalists, and the want of educational institutions for training an efficient army of expert chemists.

At the meeting of the Asiatic Society of Bengal at Calcutta on December 2, Mr. T. H. Holland exhibited a meteorite which fell with the meteor seen in eastern Bengal on October 22. The stone weighs 622 grammes, and is covered with a thin black crust formed by the fusion of the rock during its rapid flight through the air. Several stones were known to have fallen with this meteor, and the complete investment with fused crust of the one exhibited shows that fusion of the surface occurred after the break-up of the meteorite. Besides the complete proof that the meteor resulted in an actual fall of stones, special interest attaches to this occurrence on account of the observations made from so many points of view permitting the actual path and speed of the object to be calculated. At the same meeting Mr. D. Prain read papers on an undescribed Indian Musa and on an undescribed araliaceous genus from Upper Burma.

The October number of the *Journal* of the Royal Horticultural Society contains a brief description, with some illustrations, of a number of trees and shrubs recently introduced from China by Mr. Veitch, which seem to be suited to our climate, and may prove to be important acquisitions to our garden plants. As Mr. Veitch states, they have been chosen from the collections made by his agent, Mr. E. H. Wilson, and bear testimony to the latter's energy and assiduity. In the same volume the practice of watering cucumbers and tomatoes with copper sulphate in order to ward off fungal diseases is recommended by Mr. G. Massee.

The primary function of the park and garden committees in our cities and towns is to provide ornamental and open spaces. The members of the Bradford Parks Committee have recognised that it is within their province to afford educational facilities, and have set apart a plot of land in Lister Park to be converted into a botanical garden in which to present a systematic grouping of plants, and also to grow trees, and local or economic plants which will serve for the purpose of identification. It is within the scope of this scheme to provide material for teachers' use and to establish informal public lectures at which more interesting specimens can be shown and discussed.

In No. 6 of the *Publications* of the Conseil Permanent International pour l'Exploration de la Mer, issued at Copenhagen, Mr. H. M. Kyle describes a trawl-net designed to work in mid-water as well as on the sea-bed. This net, which is constructed on the umbrella principle, has been tried on one occasion at Grimsby, and, although the results were not entirely successful, may quite possibly prove efficient.

We have to acknowledge the receipt of the second part of Mr. J. Macoun's "Catalogue of Canadian Birds," published by the Geological Survey of Canada. This part includes the diurnal birds of prey, together with the woodpeckers, flycatchers, crows, jays, and American blackbirds (Agelæus). Three years have elapsed since the publication of part i. (which was noticed at the time in our columns), during which period much additional information has been acquired with regard to the distribution of Canadian birds; consequently this portion of the subject is somewhat more amplified in the present part than was the case in its predecessor. Otherwise, the mode of treatment follows the original lines.

We have received copies of the first six numbers of a series of circulars on agricultural economic entomology, in course of issue by the Trustees of the Indian Museum, Calcutta. Each number is devoted to a single species of

insect, of which it contains an illustration. In each instance the general appearance and mode of work of the insect are described, after which we have its distribution, food, and ravages, followed by a brief account of its general habits, and concluding with suggestions for remedial measures. No. 4 deals with the date-palm, or Indian rhinoceros-beetle, of which both the grub and the adult insect inflict very serious damage on the tree after which the species is named. The next part treats of the north-west, or migratory, locust, of which the distribution within the limits of the Indian Empire is shown on a map.

IN the December issue of the *Quarterly Journal of Microscopical Science* Prof. Ray Lankester figures for the first time a couple of small blind crabs of the genus Cymonomus (or Ethusa) taken so long ago as the cruise of the *Porcupine* (1869–70), and described by Canon Norman in 1873. The main reason for bringing these specimens into prominence is owing to a statement in a popular work that they belong to a species of which the form inhabiting shallow water has functional eyes, while as we proceed deeper and deeper the eye-stalks are found to be more degenerate. The statement that an eyed form exists is apparently a misconception, while the idea that the one in which the eye-stalks are the most modified inhabits deeper water than the other is likewise not well founded. As a matter of fact, Prof. Lankester believes the two specimens to indicate distinct species. The other contents of this serial include a discussion on the origin of the green cells found in a turbellarian worm (*Convoluta roscoffensis*) peculiar to Brittany, by Messrs. Gamble and Keeble, and a note by Dr. Hanna on the presence of Trypanosoma parasites in the blood of certain Indian birds. In a third article, Mr. H. M. Bernard continues the account of his investigations into the structure of the retina, dealing in this instance with the continuity of the retinal nerves throughout the Vertebrata.

IN 1902 Mr. R. Lydekker, F.R.S., read before the Zoological Society (see *Proceedings* Zoological Society, 1902, p. 981) the description of a new antelope from the neighbourhood of Lake Mwero, in northern Rhodesia. Mr. Lydekker supposed it to belong to the genus Cobus, although, as the only specimen consisted of a flat skin without head and feet, he was not quite certain where it should be placed, and named it *Cobus smithemani*, after Mr. F. Smitheman, who had obtained the specimen. Fresh and more perfect examples of this antelope have lately been received by Mr. Walter Rothschild, who has presented one of them to the British Museum. This specimen, which may now be seen mounted in the gallery, shows that Mr. Lydekker was quite correct in his judgment, and that Smitheman's antelope is a strongly marked new form of the "Kob" group, easily distinguished from the Poku or Vardon's antelope by its black neck and dark chestnut sides.

THE re-introduction of cotton cultivation into the British possessions on the Spanish Main is regarded as of sufficient importance to justify the devoting of the whole of the third part of vol. iv. of the *West Indian Bulletin* to the subject. One-third of the number contains reprints of articles, or portions of articles, in the "Encyclopædia Britannica" and in various publications of the United States Department of Agriculture. The remaining two-thirds gives much useful information bearing upon the cultivation of cotton in St. Kitts, Antigua, Montserrat, Barbados, and Carriacou; an article by Prof. d'Albuquerque on the agricultural chemistry of cotton; one by Mr. Lewton-Brain on the fungoid diseases of cotton; and an illustrated article by Mr. Henry A. Ballou on insects attacking cotton in the West Indies. Sir Daniel Morris, accompanied by Mr. Bovell, has spent the autumn in the southern States of America making an exhaustive examination of the methods of cultivation, and the preparation for market, of the Sea Island variety of cotton. The results of the investigation will be published as an extra number of the *West Indian Bulletin*, Sea Island cotton being thought to be the most suitable for the islands

UNDER the title of "The Case for Vaccination," Mr. C. E. A. Winslow gives an admirable survey of the statistical data in favour of the efficacy of vaccination (*Science*, July 24, p. 101). It points out that a single vaccination greatly reduces the probability of an attack of small-pox, postpones it to a later period of life, and renders it less dangerous if it does ensue. To ensure absolute protection revaccination is required. During the small-pox epidemic of 1871, of 734 nurses and attendants in the Metropolitan Asylums Board Hospitals 79 were survivors from small-pox attack, and escaped infection; 645 were revaccinated on entrance, and all escaped; 10 were not revaccinated, and all took small-pox. Mr. Winslow concludes, "if statistics ever proved anything, those quoted prove the protective influence of vaccination. If any fact in science is certain, it is that a successful vaccination absolutely prevents small-pox for a period of from seven to ten years, that after that period it renders the disease less fatal, and that its complete protective effect may be renewed by revaccination. The conclusion is obvious not only that the State should oblige primary vaccination, but that a second vaccination at the age of twelve ought to be made compulsory."

THE latest addition to the convenient little scientific memoirs published in the "Scientia" series by M. C. Naud, of Paris, is a translation of two papers by Prof. J. Willard Gibbs which appeared in 1873 in the *Transactions* of the Connecticut Academy, and have become scientific classics. "Diagrammes et Surfaces thermodynamiques," as the book is entitled, is by M. G. Roy, of the University of Dijon, and the translation is preceded by a biographical notice of Prof. Gibbs by M. B. Brunhes, of the University of Clermont.

MR. WILLIAM TAYLOR has recently circulated a pamphlet with the title "The Science of the Engineering Workshop," in which he urges the need for making scientific knowledge readily available to those at work in engineering shops. He then proceeds to trace—under the three headings, materials, processes, and tools—the foundation and outline of this science of the workshop. The publication concludes with the syllabus of a course of instruction, largely the work of an advisory committee of engineers, in the science of the workshop which is in use at the Leicester Municipal Technical Schools.

THE annual report of the Smithsonian Institution for the year ending June 30, 1902, has reached us, and an examination of the volume shows it to be of the same valuable character as its predecessors. The proceedings of the Board of Regents, the report of the executive committee, and the annual report of the secretary are followed by the usual interesting general appendix. The appendix constitutes nearly five-sixths of the whole contents of the volume, and comprises brief accounts of scientific discoveries in particular directions during the year with which the report is concerned, and the method adopted is to present a miscellaneous selection of papers embracing a considerable range of scientific investigation and discussion. Many of these contributions are familiar to readers of NATURE, since some of the papers have already appeared in these columns,

and others have been published in the *Transactions* of British scientific societies. Among the reprinted articles we notice—to name a few—Prof. Dewar's British Association presidential address on the history of cold and the absolute zero; Prof. J. G. McKendrick's contribution to the study of experimental phonetics; Dr. J. J. H. Teall's address on the evolution of petrological ideas; and Mr. H G. Wells's Royal Institution lecture on the discovery of the future. There are several translations from French and German of important papers also included, such as Prof. A. Dastre's article in the *Revue des deux Mondes* on the life of matter; Dr. Georg Jacob's "Oriental Elements of Culture in the Occident" from the German; and Herr Oscar Israel's appreciation of Virchow from the *Deutsche Rundschau*. Like all similar publications from the Smithsonian Institution, the volume is provided with many excellent illustrations.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN JANUARY, 1904:—

Jan. 3–4. Epoch of the January meteors (Radiant 230° +53°).
5. 10h. 13m. to 11h. 9m. Moon occults *o* Leonis (mag. 3·8).
12. 10h. 11m. Minimum of Algol (β Persei).
,, 15h. 0m. Ceres in conjunction with moon. Ceres 0° 58′ N.
15. Venus. Illuminated portion of disc = 0·707.
,, 6h. 58m. Minimum of Algol (β Persei).
27. 0h. 0m. Vesta in conjunction with moon. Vesta 0° 21′ N.
28. 4h. 55m. to 8h. 8m. Transit of Jupiter's Sat. III. (Ganymede).
,, 8h. 0m. Venus in conjunction with Uranus. Venus 1° 47′ N.

EPHEMERIS FOR WINNECKE'S COMET.—A second part of the ephemeris for the 1903–4 appearance of Winnecke's comet is published by Herr C. Hillebrand in No. 3916 of the *Astronomische Nachrichten*, from which the following has been taken:—

Ephemeris 12h. (*M.T. Berlin*).

1904	α app. h. m. s.	δ app. ° ′ ″	log. r	log. Δ

SPECTRUM OF MIRA CETI.—In No. 5, vol. xviii., of the *Astrophysical Journal*, Mr. Joel Stebbins, of the Lick Observatory, gives the results of a study of the spectrum of *o* Ceti made with the 36-inch refractor during the period June, 1902, to January, 1903, in which period the magnitude of the star decreased from 3·8 to 9·0. The spectra were obtained with spectrograph i.—which is the Mills spectrograph converted into a one-prism instrument—attached to the 36-inch, and a spark between iron poles was always used as the light source of the comparison spectrum.

The absorption spectrum obtained is not very like the solar spectrum, but the calcium lines *g*, H and K are all present, *g* being comparatively much more intense than in the solar spectrum; the iron lines are not prominent, and even the strongest do not appear when a small dispersion is employed. The *g* line undoubtedly becomes broader as the star grows fainter, for on June 27 (mag. = 3·8) its width was 2 t.m., whilst on September 6 (mag. = 7·0) it was 9 t.m. The lines at λλ 3990·64, 4045·16, 4093·55 and 4097·08 respectively, which are apparently not coincident with solar lines, appeared at successive intervals during the diminution of magnitude.

A comparison of the several spectra shows that with the decrease in the star's magnitude the continuous spectrum from λ 4300 to λ 5000 becomes relatively fainter than that between λ 4000 and λ 4300.

The bright hydrogen lines are very prominent, and Hβ and Hε, which have been reported as absent by other observers, appear on all the dense negatives, and they appear to grow relatively stronger than the other hydrogen lines, and the continuous spectrum, as the star's magnitude decreases. In addition to the hydrogen lines, bright lines of Si, Mg and Fe are probably present, and numerous changes took place in their relative intensities during the interval covered by the spectrograms. For example, the line at λ 4007 undoubtedly disappeared altogether, whilst the line at λ 4571—possibly due to magnesium—developed in a remarkable manner. The latter did not appear at all until the star's magnitude had fallen to 5·4, and afterwards it became the most prominent feature of the whole spectrum. The evidence obtained supports the conclusion that the bright hydrogen lines disappear at minimum.

Determinations of the star's radial velocity showed that it remains constant at about +66 km., and this is held to be a strong argument against the theory that the light-changes are due to the existence of a companion. The abnormal changes in the relative intensities of the hydrogen lines—which are displaced from their normal positions towards the violet, apparently by other causes than radial velocity and pressure—lead Mr. Stebbins to the conclusion that the light changes are due to internal causes which produce effects that are, as yet, unfamiliar to us.

THE "COMPANION TO THE OBSERVATORY," 1904.—The 1904 edition of the well-known annual compendium of astronomical data, the "Companion to the Observatory," is very similar to that of 1903. It contains, amongst other information, the usual tables for solar, lunar and planetary observations, ephemerides for the various satellites, and minute data regarding a large number of variable stars.

Mr. Denning has contributed a set of notes regarding the principal meteor showers, and Mr. Maw has supplied a list of double-star observations, whilst the numerous variable star ephemerides have been taken from advance proofs supplied by M. Loewy.

OXFORD AND SCIENCE.[1]

WHEN I am tired I sometimes go by train to Reading and cycle over here swiftly in the afternoon, and then I dress and dine comfortably at the *Mitre* and go out for a stroll. Perfect rest is not possible unless there is moonlight, but Oxford is always wonderful and satisfying and restful to an engineer like me. It is not because of its age, of the great men who have studied and worked in its colleges, of its almost unique character and high rank among universities, of the sacred beauty of its colleges and streets. It is because that to me it represents what is most persistent in the constitution of the British Empire. The Houses of Parliament, Westminster Abbey, the Temple and City of London, Windsor, the great mansions of our English nobles, each of these suggests much to any man who is fond of reading, but each suggests only a small part of what Oxford represents.

Now the thing that pervades all my thoughts of Oxford is that more than half of the most distinguished Englishmen during four hundred years have been educated here. And if, as I sometimes do, I include Cambridge when I say Oxford, all the most distinguished Englishmen during four hundred years have been educated here.

Whether we like it or not, it is a fact that England is an aristocratic republic with the King at the head of the

1 An address delivered by Prof John Perry, F.R.S., at a public meeting in Oxford, arranged jointly by the Ashmolean Natural History Society of Oxfordshire and the Oxford Mathematical Society.

aristocracy. There is a disadvantage in almost all our rulers being selected from a limited class. But in the democratic republics of America and Europe there is the far greater disadvantage that the nation seldom commands the public services of rich or cultured men or men of family. Here there is no man so high in rank, or so rich or so intellectual, that the nation cannot command his willing services. Again, there never in the history of the world was an aristocracy like ours, admitting new men in every generation, allowing a constant flow of its younger sons downwards. Americans may gibe, and some of the younger of us may rail, but this system of government is beloved of all people in England, rich or poor; it is so much a part of the English constitution that no student of history can imagine an England governed in a different way, and this aristocracy will retain its power over a believing people until the time comes when it ceases to believe in its own self. At any one time it is only a minority of undergraduates who belong to the ruling caste, but the important thing to think of is that practically every member of the ruling class of England passes the four most important years of his life in Oxford (or Cambridge). All the rest of his life he looks at things through Oxford spectacles. His father and his father's friends were Oxford men. His mother and his aunts have always been under the influence of Oxford clergymen; even the lighter literature and journalism of the household are from Oxford pens. Until he leaves his nursery, under his earliest tutors, in his preparatory school, in a public school, every tutor he has had, every influence round him, have been dominated by Oxford feelings.

When at an age of from twenty-one to twenty-four a young man enters Parliament or diplomacy, or any of the reserved parts of our public services, his character is formed; all his ways of thinking and his prejudices are on the models most revered in Oxford. His early youth has been influenced by Oxford of the past, his undergraduate ways have influenced and been influenced by Oxford of the present, and his prejudices, kept strong by loving memories, exercise an influence against all changes in Oxford for the future.

I have often thought that Darius and his companions, the sons of the ruling families of Persia, had a most delightful education. We do not hear much of their love for literature or what we should call school-book work. Their education was in companionship with each other and with their wise fathers and their friends; in military exercises and in sports. Young gentlemen of England have always had that sort of education. It was probably best in Plantagenet times, when, indeed, a well trained young gentleman was not only very healthy and courageous, but he had not much chance of becoming lazy; he had the opportunity, denied to the lower classes, of becoming fit to lead in warfare, fit to assist in all that then constituted the government of his country. But when the positions hitherto monopolised by great ecclesiastics became possible for laymen, if these laymen possessed the necessary learning, youths of the higher class began to go to Oxford, and in the times of Queen Elizabeth and James there was real liberal culture among them such as had never been before and has never been since. To go to the university then became fashionable, and remains fashionable with youths of our higher classes.

What is the nature of the education now given to one of these young men? His father, a man of consequence in his county, perhaps in the legislature, probably experienced in public duties, with much knowledge of men, has played with him in his infancy, and keeps in touch with him always. Even from infancy he has been in contact with the great people of his time. No book work, no lectures were needed in teaching him the manners of his class. He cannot help acquiring the virtues of the aristocrat; his personal honour is dear to him, he always speaks the truth, he scorns all meanness, he respects the rights of others of his own class, and, indeed, of all others in so far as he understands that they have any rights. He shoots well and rides well. For some generations back he has been cleanly in his person, and he has been temperate and keeps healthy of body. Whatever becomes a custom of his class he follows as a law. Loyalty to his class and to the head of it are his creed. On the other side, he is ignorant of all knowledge that has not come to him by actual observation. His sympathies outside his own class are very limited and conventional. His traditions are to the effect that only one man in a hundred takes heartily to school work, to book work, to learning; that the average man of his class does not go to Oxford for learning. He goes to finish his education, to meet and make friends with men who are to share with him later on in the government of the country. Healthy as an otter, unflinching as a fighting cock, faithful and courageous as a bulldog, clean as a cat, in far more intimate companionship with men than he ever will be again, he admires or makes close friendship with or mildly dislikes these equals. His connection with the university is small; his college is everything; tutors were created for him. He learns the value of public opinion; he learns that ginger may be hot in the mouth, and yet he is surrounded by such police arrangements that he is guarded from ruin even when he is most reckless. Truly it is a wonderful experience, a valuable education, and it is never through book work or lectures, but from actual experiment and observation that the average young Englishman ever has or had any kind of education. Darius and his young companions were well fitted to rule, but they probably could neither read nor write. The average young man who leaves Oxford with or without a pass degree forgets very soon what book work, what learning, he ever had, and he dislikes reading. He has always been laconic in speech, and finds a small vocabulary quite large enough for his needs. He has successfully cultivated an appearance of want of vulgar interest in anything, so that want of practice begins to tell upon his powers of observation, and his resourcefulness tends towards that of the ostrich. It is fondly assumed by his tutors that, although he soon forgets his Latin and Greek, yet his study of these was the medium of much mental training; that the study of Euclid and logic have given him a logical mind. I cannot deny that there may have been some mental training through Latin, but I assert—it is, of course, mere assertion—that it has not been much. On the other hand, I assert that much harm has been done, for his hereditary prejudices against all book work, all learning and literature have been deepened. For the few men of his own class who take kindly to literary studies he has a respect not untinged with doubt. Between him and the real student not of his own class there is a great gulf fixed, like what there is between him and clergymen.

Observe that I am not here referring to the education of the real students. For them, it is true in a very limited range of subjects, but for them there is the most wonderful education ever known.[1] They also make friends for life, they take fire at each other's ideals as only young men can, they meet every day the great scholars of their age who are also students, and there is always a fine education in the mere contact with men worthy of young worship. Young men like this need but little teaching; they are fond of books and educate themselves.

It is easy for an outsider to overpraise this education, because the glamour of the beautiful college life is on all his thoughts; he does not at once observe how narrow the culture has always been, and how now the examination system is cramping it more and more. Oxford is hard, unspiritual and idolatrous, and the absence of scientific method is evident everywhere. Oxford is like a technical school, training these better men for the higher posts in the Church, in the Civil Services, in journalism, at the Bar, and in boys' schools. And it is found that these successful men have dwarfed imaginations and no power to think for themselves in any subjects outside their narrow professional grooves. The barrister who seems inspired in the Law Courts is mute and inglorious in the House of Commons. The readers of the hundreds of newspaper

[1] Just nine days ago I gave a short address on the twentieth anniversary of the opening of College Hall, London. It is a hall which Lady Lockyer, her sister and her friends started for women students attending medical and other college courses where they might have that companionship without which there can really be no higher education. It is curious that this should be the only college hall in London, that London should be so well provided with university professors and lecture rooms and laboratories, and that the equally important colleges of residence should be non-existent. A great city like London needs such halls far more than Oxford did when William of Durham and Walter de Merton began to build.

articles of any morning—as like one another as herrings—are awed with their display of culture, of depth of thought, of knowledge, and with what is more astounding than anything else, an infinitely perfect Oxford polish. Watching the performances of an Oxford man of letters is like watching a good billiard player or a skilled musician. His mind is filled with the thoughts of other men, pigeonholed, ready for use. He thinks those thoughts to be his own, and he never takes in the real meaning of the fable of Diogenes and the lantern. He does really think for himself in that part of his trade which is personal to himself, and he has an abundance of all learning except what concerns those natural sciences the applications of which are shaking the social and intellectual world. He is never grossly unfair to other men who follow the rules of the game recognised by Oxford; against men of new ideas his struggle oft availeth. In dealing with some questions he is a genius towering to the heavens, in others he is like that same spirit imprisoned in a little bottle, sealed up magically by the mere name of some wise man of antiquity.

It is very noticeable that the Oxford man has retreated from the renaissance position and has gone back to the mediæval. He believes in his soul that there is no new thing under the sun; truth is not a thing to be discovered, it is something already revealed in Hebrew and Greek books. Even if a man is doing research it is after the poison has entered his system; his individuality has been practically destroyed. But for the present I am neglecting these real students. I am confining my attention to the average men of caste. These men are educated in the sense in which Darius and his friends were educated, excepting in this, that Oxford men do not know living foreign tongues, whereas the other barbarians did, and Oxford men pretend to know something of certain tongues that are dead. Every attempt to teach them by actual observation, actual experiment, actual trial, actual research, has succeeded well; every attempt to teach them by mere talk, by abstract reasoning, has failed.

And the world now to be governed is getting more and more complex. Man is utilising the energies of nature in thousands of ways unknown to the ancients. Common people are all getting educated. Where the ancients wondered and trembled, we understand and give orders to nature. The average unit of any population was compelled to be what we now call an unskilled labourer.

Now our labour is becoming more and more skilled. Are you aware that from one ton of coal there is as much energy, as much actual work, as may be done by forty thousand good labourers in a ten hours' day? Our best steam engines utilise only one-tenth of this energy at the present time. But even now we know that the cost of the most unskilled work done by man is one thousand times the cost of the same work wherever it may be done by the best steam engines. One fact of this kind properly considered is worth many long essays about the effect of the engineer in altering all the character of our civilisation. It is labour that is the true standard of wealth. The steam engine has added incalculably to the wealth of the world. We forget that man is no longer needed for unskilled labour, so that when we use unskilled labour we are using the materials which God has given us in the most inefficient manner possible. Furthermore, it becomes sweated labour, it unduly taxes skilled labour, it starves invention, and it brings up base, ill-fed families.

I do not think that a fact of this kind would have been neglected by the philosophers of Greece or the learned men of Rome, but when some of us direct attention to it and its neglect by modern philosophers, we are sneered at as Philistines; when we say that the nation which does not pay great attention to the practical application of scientific knowledge of nature must cease to exist, we are jeered at. We are low mechanical persons enacting the part of the fat boy in "Pickwick," "I'se goin' to make your flesh creep!" It is a curious kind of culture which scorns the lessons of history, the study of man in his relation to nature, the study of the enormous new forces which are now affecting the relations of nations to one another. Are you learned misers going for ever to gloat in secret over your learning or to edit for ever the same Greek texts, or for ever to spin new metaphysical philosophies out of your inner consciousness?

Are you for ever to labour over phrases and dogmas that have been endlessly discussed by the most acute intellects of all time? If through a practical study of palæontology or biology you could get really to understand the great discovery of Darwin (and you cannot possibly get to understand it from books alone), you would see that the oldest puzzles of children and philosophers, from the shepherds of ancient Idumea to the dons of Oxford, have been solved for ever. Have you for one moment any idea of the magnificent new problems that are now before us, of the wide outlook on the universe, the comprehensive grasp of what is great and what is little, which is possessed by naturalists? For one man who knows his English literature, who revels in Shakespeare, are there not ten in Oxford who scorn all literature which is not at least 1800 years old? If you must meditate about your thoughts and emotions, why not begin with some experimental psychology? Why is there so little research of any kind in any subject going on in Oxford? The study of the Greek language through Herodotus is called *history*. The study of the Greek language through the early fathers is called *theology*. The New Testament is degraded into a Greek text-book. The Iliad and Odyssey are only Greek exercise books. The clear gushing spring of the desert beloved of Erasmus and More is now trampled into dirt by innumerable dromedaries. Is it any wonder that the average healthy young Englishman whose common sense has been developed through observation and trial should leave Oxford ignorant of your sand-ploughing scholastic exercise work? You have thought him stupid, and made him believe himself to be stupid, when he was only showing his wisdom. The mental training that he might have had, that he needs in life, that kind of training which his ancient Persian education cannot give him, where is it? When he was a very young boy you tried to teach him arithmetic for years, a cruel exercise. Now he does not know what a decimal is; when he borrows money at 5 per cent. per month he does not know that he is paying 60 per cent. per annum. If you had let him experiment, play at keeping shop, actually weigh things in ounces and pounds, or pay for them in shillings and pence, if you had let him measure things in inches and tenths of an inch, it would have been a pleasure for him to learn. If he had spoken French and German, and had been encouraged to chatter in those languages, he would not now be so ignorant. If you had encouraged him to read stories, if later you had not made all reading a school task, if you had encouraged him to describe things, to write accounts of what he had seen; if you knew how to teach anybody English, the language of his country, if you had refrained from putting geography and history and other English subjects all in water-tight school class compartments, he would now be fond of reading, he could use books, and he would go on educating himself for the rest of his life. You made him wear his soul out in learning off Euclid by heart—why did it not strike you that he ought to draw and measure, weigh and experiment, long before you tried to give him abstract reasoning of any kind? How is a boy to reason about things unknown to him? In the nursery he got mental training through everything he saw, everything he clutched. Oxford took charge of him scholastically at the age of seven, and from that time onwards his higher mental powers ceased to grow. His mental equipment suggests the item for bread in Falstaff's famous tavern account.

And he becomes a ruler of this great nation, his duty during war and peace being that of a scientific administrator. Times of actual war are few and short; in those times the people and property of unprepared nations are destroyed with a rapidity never known in the past. In all old times England was unprepared for war, but this did not then so much matter; in future the nation that has not prepared during peace for possible war, by the exercise of the highest scientific faculty, will certainly be destroyed.

I am afraid that Von Moltke would have laughed at the kind of education of Darius and his friends being regarded as sufficient in these modern days. Also the war between nations is quite intense in times of peace. The rulers of nations have to take care that their laws do not destroy

industries, that they develop the right sort of education of the people; that the people shall be so educated as to become resourceful, full of initiative and invention, capable of learning from experience, people of character. Again, if our rulers set a fashion of gibing at scientific things, at technical education, for example, through ignorance, it is not unimportant to know that the complete loss of trades like the coal tar industries may be more serious evils than the loss of several campaigns in war used to be. If the Prime Minister, or any other minister, gives an important post to a non-scientific man, it may not be harmful, but sometimes it may be very harmful indeed; it may lead to the appointment of many unscientific men or the disgrace of the scientific men already engaged in some department where science is all important. But the evil is very much more far reaching than one can describe in words. Want of science in the rulers means neglect of scientific education and method throughout the whole country.

For your man of caste is an Oxford man, and as a ruler of his country he regulates all sorts of courses of instruction and examinations for the army, the navy, the Civil Service, the Indian Civil, the Colonial, and all sorts of other services, and he takes care that all these shall be on Oxford lines. The higher permanent officials are chosen by Oxford standards. The members of scientific committees appointed to assist Government departments are chosen by Oxford standards. Do educational experts suggest reforms in education, it is Oxford that determines whether the reform is received sympathetically or otherwise. Probably nowhere is the influence of Oxford felt more than in the primary schools of the country.

I know you are proud that Oxford should have so great an influence, and I do not suppose you will pay any attention when I suggest that it may lead to national misfortune. If Oxford scholars were merely like so many monks in their monastery, living the lives, following the studies which they love, I would say nothing. The revenues so used up are, I think, of no great importance to the country, and busy men elsewhere can only be benefited in knowing that there are these lovely lamaseries where men are living in serene air apart from the struggles of the world, living what they think to be the higher kind of life, that of the amateur copying the lives of the scholars of Constantinople before they were so mercifully scattered in 1453, copying the meditative ways of the divines and hermits of the fourth and fifth centuries.

But the Oxford hermit is also a ruler of an empire in the twentieth century. Edward the Confessor was a saint, but some of us think that he was not a very wise ruler of England. Louis XVI., too, was an amiable man. The downfall of nations has generally come from the too great power of some quite amiable amateur persons or corporations. It is mainly through her too great influence on the ruling families of England that I consider Oxford to be dangerous.

What, then, is it that we want? We affirm that all so good as the development of the faculties of the average Oxford man may be, it might be enormously increased. He learns by observation and experiment; he and his forefathers have never learnt anything otherwise. Why not, then, increase for him these chances of observation and trial? Frankly confess that to develop his reasoning faculties through mere repetition of the text of Simpson's Euclid is an absurdity, that he cannot at all take in abstract reasoning; that the academic methods of teaching mathematics and its applications are what we all know them to be, mere frauds. Some of our Chancellors of the Exchequer are known to have been ignorant of arithmetic. There are fine jokes—jokes understood even by board school children—told about Foreign and War Ministers of England who were quite ignorant of geography. "Bless my soul, you don't say so—Actually Cape Breton is an island—actually. I must go to the King at once and tell him that our great expedition has been sent to an island!"

These are no longer jokes to me; I merely feel that it is extraordinary that a man can have been so educated as to be a good debater, to be able to make a fine speech, that he may have taken a degree at Oxford, that he may have passed examinations in classics, philosophy and mathematics, and yet be exceedingly ignorant, illogical, unscientific, and unable to do easy computation. Some of us say that it is only through the experimental study of natural science, and not at all through the classics, that the brain of the average Englishman can be educated on that side which is never educated at the present time. We say that he is never taught English, yet history and English literature are finer mediums for his education than ancient classics. We say that if when young he was taught to be fond of reading English—and every child may be made fond of reading—later on he would be able, and very willing, to use books, and that a man who is fond of reading and is able to use books keeps educating himself all his life long. But books alone at Oxford are not enough. They are not wise the men who think that lectures and books alone, and observing lecture-table experiments, can give men an acquaintance with the great discoveries in natural knowledge which are revolutionising the world.

Do you know the ballad about the Count Arnaldos who envied the old helmsman his weird and wondrous powers?

> "Would'st thou, thus the helmsman answered,
> Learn the secret of the sea,
> Only th se that brave its dangers
> Comprehend its mystery."

I know there are many men in Oxford who think, like the wistful Count, that they can get all things easily or from mere reading. But, in truth, to read "The Origin of Species," or treatises on geology or astronomy or physics or chemistry is a misleading performance unless the reader brings to the study that kind of mind which has been developed already by his own observation and his own experiment. My classical friends laugh at me when I say that I know much Greek literature through translations, and yet they pretend to be able to weigh scientific arguments without having made any practical study of science. At all events I know my defects. I know that although a translation may give me in every particular the meaning of a Greek author, it cannot give me the music of the old language; the reasoning and facts are mine, but not the emotion. And when my classical friends say that they can weigh scientific arguments I laugh, for there are parts of those arguments as much beyond their comprehension as scientific evidence is beyond the comprehension of a Chancery Court. Who can compete with a barrister in reading, in extracting the meaning of a written document? and yet barristers fail utterly in getting scientific knowledge from books.

Besides the aristocratic undergraduates you have a larger number of middle class men at Oxford who will succeed their fathers in the management, not merely of landed estates, but of much more valuable estates in the distribution and manufacture of things. The education of these men from infancy has been on the same lines as that of their superiors, but it has been much more artificial, and remains much less thorough to the end of the Oxford course. There is, however, the same contempt for books, for learning, and the same absence, not merely of knowledge of natural science, but of those scientific habits of thought and methods of approaching problems which experimental research tends to produce. They are proud of being Oxford men, and are even more strongly imbued than the others with Oxford utilitarian prejudices. They have studied mathematics—mathematics is useless in business. Natural science was said to be taught at Oxford, and no man seemed one bit the better for having studied it—natural science is useless in business. These men become the owners of factories the spirit of which ought to be scientific research; the competing factories in Germany, France and America are run by men of scientific method, and our men discourage reform in every possible way. The rule of thumb of their fathers and grandfathers is good enough for them. Their factories are so badly arranged that the works cost of any manufacture is twice what it ought to be, and the time taken is twice as great. They take eagerly to all sorts of quack remedies for bad trade; they are easy victims to fraudulent persons. These are the men who discourage all education in the people employed by them, managers, foremen, and workmen. They are what I call unskilled workmen, that is, unskilled owners of works, and it is Oxford which is to blame for their unskilfulness. It is astounding how quickly the thriving businesses of the fathers are decaying, how quickly unskilled owners of works are being eliminated,

but there is a new crop of them every year. The want of education of these men is very harmful to the country, and Huxley, Lockyer, Armstrong, Ayrton, Magnus, and other educational experts have written at great length upon the subject over and over again. If I thought that the expression *technical education* were understood at Oxford, I might, perhaps, try to ventilate this part of my subject, but it is quite misunderstood, and as these writers have failed to make any impression I think it better to let it alone.

Fifty years ago the Prince Consort started many good things agoing, and probably the most important was the Science and Art Department, the science classes of which under Sir John Donnelly forty years ago, greatly developed by Sir William Abney since, have given a better education in natural science to hundreds of thousands of poor boys than Oxford gives even now. I feel sure that it is this that has saved our industries from the jealous, hungry, persistent scientific foreigner. Wherever there is an owner of works whose common sense triumphs over his defective education, he gives a free hand to a manager who has been taught in these classes or in one of the technical colleges now springing up. These technical colleges are the natural outcome of Sir John Donnelly's work. I am glad to think that their methods are far removed from the soul-destroying methods of Germany; they are gradually becoming more and more perfect as British institutions. They illustrate the British experimental method of tackling an important problem. The one bar to their success is that the boys from all the schools of this country, primary and secondary, but particularly from those schools which are more immediately under Oxford influence, are quite unfitted by their school training to benefit by technical college teaching. The time of the professors and instructors is greatly wasted in correcting evils that are due to the schools. I think on the whole, however, that middle class England is slowly waking up to the importance of education. Every kind of education she has seen in the past has seemed to her not worth striving for, and her sleep has been very sound and very prolonged. But a kind of education is now being exhibited to her which seems as if it might give a fine sort of mental training, and as soon as middle class England sees this matter clearly as a thing worth having, the rule of old Oxford over many of our schools will cease. For Oxford has not merely induced neglect of science; she has been its active enemy pretending friendship. What schoolmaster from Oxford is there who does not see his existence threatened by science? Consequently, middle class England has been paying large premiums with its sons and yet seeing them fail to obtain employment, whereas board school boys are successful enough in reaching lucrative positions, although they have paid no premiums, and have been earning wages all their lives."

It is not the schoolmasters, it is the engineers who have been educating England. The engineer is always thinking of utility, of the value of time, of the fact that a man has only one life in which to do what good it is possible for him to do. So he reads novels and poetry and history; he enjoys painting and music; he travels and sees other people, other nations and their monuments. He cultivates and exercises the whole of his mental and emotional machinery so that he may become more perfect as a student of what Goethe called "the living mantle of God."

Everybody speaks of how the engineer has created what is called modern civilisation, has given luxuries of all kinds to the poorest people, has provided engines to do all the slave labour of the world, has given leisure and freedom from drudgery, and chances of refinement and high thought and high emotion to thousands instead of units. But few seem to see that the engineer is educating the imagination and poetic faculty of England. Every unit of the population is becoming familiar with scientific ideas, for he can hardly take a step without becoming acquainted with romantic steam engines and electromotors, with telegraphs and telephones and steamships, with drainage and waterworks, with railways, electric tramways and motor-cars. Every shop window is filled with the products of engineering enterprise. It is getting to be rather difficult for people to have any belief in evil spirits and witchcraft, and this is probably the most enormous intellectual stride that the great body of the human race has ever made in any half-century. It has been made in spite of the persistent opposition of Oxford.

It is due to Oxford that the interest taken in natural science by the richer classes, by men of expensive education, does not seem to be much greater now than it was thirty years ago. Some of them are called scientific if they go to hear lectures illustrated with fireworks, or if they assume as their eyes glance over a quasi-scientific article in a magazine that they are taking an interest in science. But among the less rich classes, the people who work with their brains, there is an interest now in science which is increasing in amount by the compound interest law. This new interest is recognised in the fine idea of Sir Norman Lockyer, so well talked about this summer, to form a great British Guild of Science the members of which might include almost every adult man or woman of brains in our Empire. His object is to organise the efforts now being made everywhere to interest people in science, to develop education in scientific method in every school in the country. I feel sure that this Guild will some time be formed successfully, and that it will do enormous service to the world. Its being successful in our own time depends mainly, I think, on the energy and persistence of Sir Norman Lockyer himself, and he certainly is an energetic man. May I ask if Oxford means, in her place of fancied security, merely to look on at great scientific movements? Or may it even be that she will use her autocratic authority to put all these movements down? Will she, in her pride, champion another lost cause? Or has she a sufficient number of young able men rich in the sort of enthusiasm possessed by William of Waynflete or William of Wykeham, by the pupils of Grocyn who did not lecture to Erasmus, or of Colet, the Dean of Eastminster. Just think of it you Oxford men, you who have entered on such an enormous heritage, you who have been supposed to stand for centuries at the head of the intellect of England. Are you now going to stand aside or are you going to oppose the greatest intellectual movement that has ever taken place in this world—or are you going to take your natural places in the foremost files of time?

If Oxford taught science through a student's own research, if Oxford gave a broad general culture suitable for all sorts of men of all sorts of minds, there is hardly any middle class man in England who would not be glad to send his son to Oxford. Even now the prestige of Oxford and the social advantages that it offers overweigh in the mind of many a parent all the intellectual disadvantages.

A man must be very impudent or very bold, or he must have much of the martyr in him, to criticise corporations like those which exist in Oxford. He must feel his cause to be infinitely right, because Oxford men have always been famous for their command of rhetorical weapons. There is hardly a man worthy the name of scholar in Oxford who has not a better command of such weapons than I. Think of the time when Oxford had fallen from her high estate in scholarship, so that Boyle and Atterbury had the same sort of ignorance of Greek which Oxford men now have of natural science; yet were these impostors so clever that they set all the world laughing at Bentley, the greatest scholar of a hundred years. Am I to be the fresh victim of the Bull of Phalaris?

Call it impudence if you please, but Oxford ought to be told what some outsiders think in this matter. She that represents all that is best in England, does indeed in some respects represent what is worst. Every young Oxford man is like a knight who sees only how beautiful is the lady whose colour he wears, and he forgets that the lovely body does not always cover the soul of Una; sometimes it hides the evil witch Duessa.

I do not address average men. I speak to those clever young men whose names are known now only in Oxford, whose names will in the future be carried on trumpet blasts over the world and for long time to come. Surely you aim at the study of those great eternal truths about man and nature which are hidden from the common view by prejudices; and surely you know that Oxford prejudices, however consoling they may be to your self-respect, however secure they keep you now from adverse criticism, are after all mere formulas and of only limited application, both in time and place.

You will say that I also have my prejudices, which urge me to ask if you wish for ever to look at man and nature through Greek spectacles. Well, I certainly cannot worship at Greek shrines. If Jowett's translation is the real Plato I can see none of the infinite depth of thought that my friends rave about; he seems to me pretentious and shallow; and when Aristotle speaks about things of which I happen to have some special knowledge, he seems to me so unscientific as to be maudlin. Macaulay somewhere says that the account by Thucydides of the retreat of the Athenians from Syracuse is the most affecting episode in history. Well, I have a great respect for Macaulay, and I have tried to cultivate a love for the people of the city of the Violet Crown, but I know some crimson patches of Macaulay's own which seem to me to be to Thucydides what Swinburne is to Shenstone. What is a fair man to say when he hears his friends talk of the greatness of Sophocles and Euripides and Aristophanes in the original, if he knows that these friends never read Shakespeare or Jane Austen or Goldsmith or Dickens? I feel ungrateful as I speak, for I have enjoyed the reading of Bohn's "Odyssey" and many another translation from the ancients as much as anything modern. Yet I cannot help acknowledging a suspicion that this worship of Greek is like one's fondness for the rhymes, often rubbishy rhymes, that associate themselves with our infancy and boyhood, or like Johnson's belief that his wife was amiable and beautiful. Have I, therefore, prejudices against Greek which prevent my seeing things from an Oxford point of view? I think not. At all events I can respect it, for I know that the other point of view has been held by some of the greatest Englishmen, and this alone is sufficient to give me diffidence. But whatever diffidence a man may feel in the expression of his opinion, he is sometimes compelled to put it aside. Not once, but many times in preparing this address upon Iceland and its snakes have I felt how stupid I was to undertake it, but it was too late to withdraw.

You will say that I, a man of little culture, am very poorly qualified to speak of reform to cultured Oxford men. Do you think that Jonah was particularly cultured when he was called upon to urge reform upon the rich, the intellectual, the high descended people of Nineveh? I do not speak to conscious Oxford. It is something altogether subconscious in a human being or in an institution to which we really speak when we expect reform. It is to subconscious Oxford that I speak, that dumb unconscious soul which has, on the whole, guided her rightly through the centuries in spite of all the visible long-continued eruptions of the flesh. Many colleges have for generations in the past been given up to eating and drinking and sensuality in general. Jealous quarrelling has ruled in her common rooms. Poor thin scholarship has often had unworthy victory. But the heart of England is beating in Oxford, and on the whole it is a very sound heart.

Now it seems to me—a rank outsider—that Oxford is cursed among universities in one very important particular. There has in the past been only one kind of real study here. Whatever was studied in Athens or Alexandria to the end of the second century A.D., that has been open to you, that has been a medium of mental training. But those subjects in which Germany has made her mark, theology, law, history, Bible criticism and others, these are denied you.

Who was it who first pointed out how England differs from France in one important particular? The French Revolution has made such a complete severance of the modern from the old French system that a French philosopher can discuss French history as if it were of another planet. When he speaks of the old provincial Parliaments or the edicts of St. Louis, his prejudices and interests interfere in no way with his reasoning. When he discusses the present Concordat or the *Coup d'État* of Napoleon, he makes no reference to the times of Philip Augustus or Louis XIV. But in England it is quite different. When the lunacy regency in the time of George III. was being discussed in Parliament, all the precedents long before the time of Henry VI., even back to the time of Edward II., had the force of legal documents. The Parliament and ministers of Charles I. both appealed to English history, and both found support for their very divergent views, and so English history has to be read and written with the bias of modern political party spirit. In the same way the student cannot touch the questions of theology or law without considering them as party questions. A subject which can only be approached by a student with prejudices evoked by the party politics of his own day is distinctly not a subject through which university culture is possible; I mean that it cannot be studied scientifically. Theology presently becomes mere dogma, and degenerates into credulity as the glory of the church is more important than truth. Thus it is that the scientific students at Oxford have confined themselves to the study of eight or nine old books. Never, perhaps, has there been so wonderful a phenomenon as this, the cleverest men of a nation devoting themselves for centuries to one narrow stream of erudition, making Greek literature and Greek philosophy phosphoresce in the most brilliant manner. But it is too narrow, this stream, and the laws of the game are too technical, too artificial. Consequently, every now and again something like the fidgets, the desire for something real to think about, seizes upon the Oxford community; it throws itself into politics or tractarian movements, it is strongly conservative or strongly liberal, it is high or broad or low, and, after a splendid display of energy, the fever works itself out, and there is a gradual return to the older learning after a time of unintellectual laziness. In these times of fever, as in the time of the Tracts, real study falls to its lowest ebb, because truth of any kind has ceased to be an object of worship. If I am right, then it is the leanness of the studies which are really scientific which causes these great alternations, these periods of degradation, these times of easy conscience when that freedom which is the glory of Oxford degenerates into licence. You know quite well that there must be such degeneration unless men have healthy, delightful work to do, and there is a healthy public opinion to be feared or welcomed.

Such attacks as those on the fair-minded Gibbon and examples such as that of the very much prejudiced Froude show how difficult it is for any Englishman to make a scientific study of English history, or English law, or English, or, indeed, any kind of Christian theology. Indeed, in the study of mental and moral philosophy of the *a priori* kind, according to any school from that of Socrates to that of Kant, it is difficult for an Englishman to keep clear of dogmatic theology and partisanship.

But the great world of natural science remains, the region in which no attention whatsoever need be paid to sacred books, to dogma, to authority, the region in which the mind feels no fetters, where no kind of individuality is a crime, a world of promise in which the first pioneers have already in a short time found great stores of wealth on the mere surface of the ground, a world which seems infinite in its possibilities. It is only in this free atmosphere that the mental constitution will become healthy enough to be able to combat prejudice and the dogmatic microbe. Talk no more of man as if he were apart from nature. The mind, the consciousness, the soul of man and all his emotions are natural and to be studied by the deductive and experimental and inductive methods used by us in all parts of natural philosophy. Give up this mere absorption of other men's ideas, whether in old classics or in quarterly and monthly reviews, this collecting of ready-made opinions on all subjects whatsoever. Are you for ever to hang to the apron strings of the ancients? Is your manhood worth so little that you cannot exist without worshipping men who were creatures like yourselves? You speak of the reason of man as if it were an omnipotent thing. We speak of the spirit of God in man brooding over phenomena which seem chaotic until new light is evolved and you actually think that we are beggars living upon scraps of wisdom dropped from your tables. When you insist upon your classical tests you spoil our whole scheme of study, and you are merely acting as brigands, you are only taking that sort of *advantage* which all mean people take when they have official positions.

It is not learning that is important. A university is to create men, men of original thought, men of character, men of resource, men fond of reading. And you men of the university as distinct from the colleges—if you really can invent some examination which will select the men of thought, do so, and use it, but for my part I do not think this business of selection one for

any kind of machinery that ever yet was invented. There is too much of the ludicrousness of Teufelsdrüch's iron king about all schemes of examination that ever I have known, and there is too much of the draper's assistant style of work about your boards and committees. If you have any really important piece of work to do, give it to some one *man* to do, and ask people to discuss it at a public meeting; but this committee kind of pretence of work is getting to be ridiculous. You are certainly wasting the time of the few good men and giving easy consciences to all the other men who attend these boards.

I hold a brief for the average man usually said to be stupid, and yet I have been speaking of scholars, the rulers of the university, the men to whom younger men look up with worship. This is because there can be no real teaching unless some of these higher men are really great students themselves. Never did men have as good a chance of education for themselves as the fellows of the rich Oxford colleges; never had men such a chance of merely marking time and pretending to educate themselves.

About seventy years ago teaching began to become the very valuable monopoly of the college tutors. This could hurt, but could not destroy, the effect of college life in producing liberal culture. The college don ceased to be a student, he tried to teach many different subjects much in the style of the fourth form master in schools; he prepared men for Responsions, which is really a sort of belated matriculation examination; clever men may still pay him fees, but for them there is only harm in attending his classes. Hence it is that for thirty years you have been returning to the ancient practice, and the number of university professors, of lecture halls and laboratories is slowly growing. Surely this is the direction of true reform. Is it not possible to get each rich college to establish two or three great schools in which only two or three subjects may be studied by men through their own research, commanded by men of the highest talent and initiative, who are free to teach as they please and to examine as they please? But what chance is there of this or any reform? We have reached a time when the good men are discouraged and the bad men are triumphant. The powers of Arimanes set themselves against the powers of Oromasdes, disputing reform, and there have been many signs during the last fifteen years that the powers of darkness, those opposed to science, have organised themselves more scientifically than the powers of light. They have determined that in the future no change shall be made in the character of Oxford studies.[1] They do their best to make past reforms operative only for evil. As for the reformers, their conception of a university is of one in which there are so many literary and scientific subjects taught that every student can obtain, through the study of few or many of them, the most perfect training of which his mind is capable. Some of us have the belief that the average mind is capable, by training, of becoming immeasurably richer than even a few exceptionally great minds have ever been.

By the study of a subject I mean not merely listening to lectures, not merely using books, not merely a student's own research, or discussion with other men whose courses of study may be the same or not the same, but all this and much more, the most important after research being the worshipful study of great men whom the student is privileged to meet and possibly to work with. I mean also that a youth ought to have had a previous training fitting him for university study. There are few boys who might not be well trained at the age of fifteen; in my opinion ninety per cent. of Oxford undergraduates are at present quite unfit for any kind of university study.

I now come to a question in which I stand alone, and I beg your patience. My best friends seem unable to criticise me, for they find it impossible to get to my point of view. What ought to be the nature of the matriculation examination? I wish I had half an hour in which to try to convince you that its sole object is to test whether a student is likely to benefit by *any* of the university courses of study. Surely this was the mediæval idea; the one compulsory subject was Latin, because all the literature known to students and teachers was in Latin; all lectures were delivered in Latin; all teaching was in Latin. Consequently, in some Oxford colleges a man was fined if he spoke in any other tongue. Surely it was a good time when all learned men in the world spoke the same language. Then came the time when there was still no English literature, and not only was the best literature in Greek, but Greek was the only approach to natural knowledge, so Greek also was compulsory, and so it has remained to this day—to this day, when English literature is of greater worth than any ancient or, indeed, any other modern literature, when all teaching, all lectures are given in English, and when our English knowledge of natural science is not only infinitely greater than anything possessed by the ancients, but it enables us to say that the ancients were hopelessly wrong, when nobody except the official university orator or some traveller ignorant of the language of a foreign country speaks Latin, and speaks rather the Latin of Stratford-atte-Bow than the Latin of Rome! Three hundred years ago the rule was reasonable and necessary, but to insist on its observance now, when it is stupid and unnecessary, seems to me quite unscientific.[1]

I would therefore make a knowledge of Latin or of Greek compulsory only on students of certain subjects, and the professor ought to impose the condition, not the university. Again, students of certain other subjects ought to be supposed to know one or more modern foreign languages, and, indeed, it seems to me that the professor in each subject has a right to insist, if he pleases, on his students having certain special knowledge before they enter on the study with him. I would give him this right because I want him to have perfect freedom. But to enter the university, merely to matriculate, surely the compulsory subjects ought to be as few as possible. It seems to me that the most important thing is that every student should have had an early education through his own language, English; should be able to write an account in English of anything he had seen; should have some acquaintance with what are called English subjects, such as geography and history and the principles of natural science, and the power to make simple computations. All the teaching is to be in English, all his companions speak English; there are good English books on all subjects, there are English translations of all the good books that have been written in foreign languages.

I am afraid that no Oxford man can understand the following statement, which I make as a man of some experience, speaking with a full sense of responsibility. So abominable do I think *compulsory* Latin or Greek, or French or German, that I believe a board school to be a much better school than any other for a boy if he is fitting himself for any profession in which applied science is important.

I can understand why Tom Sawyer and his friends, when they started their gang of robbers, initiated them through passwords and a ritual. That was for "side." The gang did not consist of pirates or robbers; they were innocent young boys, and their passwords and ritual were the essence of the romance of the thing. This compulsory Latin and Greek for the average youth at Oxford seems to me merely grown up Tom Sawyerism, and it is allied in obvious ways to the worship of mumbo-jumbo. It used to be that the use of fur on clothes was reserved for the higher classes. At another time gentlemen only were allowed to wear swords. In China and Japan certain buttons and coloured dresses indicated certain rank. In our own time there are fashions of slang which distinguish the smart set of society. The survival of Latin and Greek as compulsory subjects is very much the same sort of thing. It

[1] Throughout this address my hands have been tied so that I may not make particular references. But suppose I were to provide money for the endowment of a valuable professorship of some scientific subject, do we not know what the Oxford authorities would do with it? They would appoint as professor a man who had never done any scientific work, who can never be expected to do any scientific work, who never wants to do any scientific work, and whose highest ambition will be to act zealously as the bursar of his college!

[1] It is very interesting to me to note that on the very day when I wrote this sentence, after dinner, amusing myself and not in any way for the purposes of this address, I happened to be reading the "Life of Plutarch" written by the Langhornes, and these words caught my eye:—"Another principal advantage, which the ancient mode of the Greek education gave its pupils, was their early access to every branch of philosophical learning. They did not, like us, employ their youth in the acquisition of words; they were engaged in pursuits of a higher nature; in acquiring the knowledge of *things* They did not, like us, spend seven or ten years of scholastic labour in making a general acquaintance with two dead languages. These years were employed in the study of *nature*, and in gaining the elements of philosophical knowledge from her original economy and laws."

has no more to do with education than the two hind buttons on our coats or the wigs of our judges have to do with convenience. These three kinds of school training—in one's own language and literature, in the principles of natural science, in common-sense computation—are absent from all public schools at the present time; it seems mere impudence in me to make them the only compulsory forms of training for men who are to enter a university. Until this is done, I think that most of the endowment of science scholarships is quite wasted.

I agreed to give this address because I knew that Sir Norman Lockyer intended in his British Association address to propose a very large Government endowment of the universities. At first sight his suggestion that 24 millions of pounds should be devoted to this purpose seemed ridiculous, but careful study has brought many thoughtful business men round to the idea; it is not utopian, it has actually a good chance of being carried out.

I saw, as many of my friends see, that the one thing which may wreck the project is the reputation of Oxford. Our rulers who have to grant the money know of universities only through their knowledge of Oxford. It is hardly possible for them to understand what we mean by a true university, which would give to every student real breadth of culture, real mental training. They may be brought to see it if Oxford men are in earnest in trying to develop Oxford on scientific as opposed to unscientific and ill-regulated lines; if the powers of light organise themselves as scientifically as the powers of darkness are organised. But there are certain intellectual movements going on in our nation which may force our rulers to grant the money; Oxford seems to know little about them and to care less; they seem to her to be merely a new untying of the bags of Æolus; it is my belief that if Oxford knew more about them she would build an altar to the goddess of *Fear* and offer sacrifices upon it, yea, burnt offerings of some of her best-loved possessions.

Oxford has a well earned prestige and still attracts all young men of intellect, but these new intellectual forces may quite quickly destroy the reputation which has been built up during centuries. For example, we have a new kind of secondary school, of which some five hundred have been established all over the country in the last few years. I myself think the science schools, scheduled as A schools, to be much the best of them, but the most numerous of them are the B schools, in which there is some natural science taught through boys' own research, but the time devoted to it is not much more than what is sufficient to enable us to say that in these schools boys are greatly emancipated from the old Oxford limitations. These schools before their emancipation sent many a fine scholar and mathematician to Oxford and Cambridge. They still rank below the great public schools. What is aimed at is an education which may suit any kind of boy, a real liberal education such as the older schools know nothing of. It is even hoped that shortly somebody in one of these schools will discover how English may be taught to English boys. All these, like the science schools, are due to the work of Sir William Abney. Now the boys of these schools, when they leave, wish to complete their education on the lines on which they have been working so far; are these exceptionally able students to be told that Oxford cannot complete that education? Few people seem to be aware that the growth of these schools indicates a great revolution; anybody who notes their rapid growth must feel sure that in a few years no secondary schools, except a few of the public schools, will continue to work under Oxford traditions. It ought to be noticed that unless boys in future are prepared on these new lines, it is not worth their while to enter Woolwich or Sandhurst, or the Admiralty colleges, because they will not be able to follow the higher instruction there given, and must drop out of the race for commissions. It is evident that the days of special army and other classes in schools are numbered. If Oxford by holding aloof from this movement ceases to influence the majority of the secondary schools, it will lose its influence over a great body of people of the middle class.

I have already mentioned another great movement from which Oxford is holding aloof, the movement for technical education the basis of which is the sort of study trifled with, feared, and hated at Oxford, natural science. It has spread from the very lower classes to the lower middle classes, and better and better buildings and apparatus, and better paid teachers indicate the higher and higher social position of the pupils of the technical schools. A few Oxford men have greatly helped in starting both of these great movements, and Oxford as a whole, if she cared, might be in a position to take a leading part in them. She has an influence now due to the easily interpreted fact that Oxford men occupy many of the higher posts connected with both of them.

It is not only that Oxford keeps aloof from technical education, but she keeps aloof from the very much greater thing of which this movement is only a symptom, namely, the phenomenon that trade and manufacture are no longer left to themselves as they used to be; they are being organised on scientific lines in all countries. She has always ostentatiously held herself aloof from manufactures and commerce. It is almost incomprehensible that a university aiming at breadth of culture should scorn those things which keep England in her high position, give value to the real estate on which Oxford's own revenues depend, and differentiate Oxford from Beyrout. I feel sure that this attitude ought to be quite carefully veiled if Oxford is to have such a share in the 24 millions as her prestige would otherwise warrant her demanding.

The truest stories about man are the fairy stories; they are true of all times, of all races of men, and the truest fairy story is that which tells how men who look back and not forward are turned into lumps of rock or pillars of salt.

I want the forces of light at Oxford to organise themselves to teach Oxford how she may become worthy to maintain the reputation which she earned so well in the past. Her great glory is *not* in her defence of lost causes as many men think. Was the movement started by Roger Bacon a bad cause? Is it a lost cause? Has the movement started by Grocyn and Colet become a lost cause? Has the movement started by those Oxford men who founded the Royal Society become a lost cause? Are the names of Wycliffe and Wesley forgotten? Have the reforms started by Stanley, Jowett and Pattison in our own times become lost causes? Not yet! The influence of Oxford over intellectual England used to be supreme, it is still enormous; it rests with the young Oxford men of the present day who know something of history tc decide whether this influence may or may not become a cause lost beyond all chance of finding again.

A NEW GERMAN BOTANICAL SOCIETY.[1]

THE publication of the first report of the meeting in Berlin of the Society of Germans interested in the Study of Systematic Botany and Plant Geography calls for more than passing notice. The society owes its creation to a well-founded cause, and is indicative of a response to that spirit of colonisation which has shown itself in Germany more and more during the past thirty years. In the first half of the nineteenth century the British Government, merchants and others were calling out for information as to the character of the flora of our colonies, and, as a result, British botanists were mainly engaged in the study of systematic botany, while the German botanists were occupied in the investigation of the structure, physiology and pathology of the individual plant, with results in each case well known to all serious students of botany.

The German systematists do not take a prominent place at the meetings of the German Association for the Advancement of Science, and though in their new society they propose cooperation, if possible, with it and with the Deutsche Botanische Gesellschaft, they seem to feel the necessity of a separate society to meet the requirements of their own branch of botanical study, which, during the last twenty years, has made enormous strides. Explorers have been sent out into all parts of the globe, and not simply to the German colonies. Listening to the papers from day to day it seemed that, so far as the conference was concerned, the

[1] Bericht ü. d. Erste Zusammenkunft der freien Vereinigung der systematischen Botaniker u. Pflanzengeographen zu Berlin. Pp. 83. (Leipzig: W. Engelmann, 1903.)

German flora might have been almost non-existent, so wide is the field covered nowadays by German investigators. Nor is this outlook due simply to the desire to know more of the economic value of their colonial floras. The more complete our knowledge the surer will the foundation be laid for that natural system of classification which so far has been most nearly reached in Engler's "Pflanzenfamilien." These two objects, increase of knowledge of the economic value of particular floras, and the reduction of the imperfection of record of the world's flora, in time and space, were kept prominently before the conference. It was refreshing to an Englishman to hear the various readers of papers acknowledge the work of the Hookers, Bentham, and others. A third object in starting the society was well carried out—to bring together the systematists in Germany, &c., for semi-scientific and semi-social intercourse.

Each evening members, accompanied in some cases by ladies, met in a restaurant for dinner, the most enjoyable of these functions being the one in Potsdam, ending a long day's excursion in the forest on the banks of the Wann. See. After an explanation of the plans for the new herbarium, &c., to replace the overcrowded botanical museum and the old gardens in the city, a visit was paid to the new gardens in the suburb of Dahlen. Here, as in the old museum, it was interesting to notice not only the grasp the director, Dr. Engler, had of everything, but also the way in which he brought forward the officers of the various departments, and left them to tell their story. Appreciation of the importance of the protection and preservation of special plant habitats or of special individual plants, and also of beautiful scenery, was illustrated by a paper by Dr. Conwentz, who for three years past has devoted his time, at the Government's request, to the study of the question, and is now engaged in the preparation of an illustrated elaborate report. The next meeting of the Society will be held in Stuttgart on August 4–7, 1904, and should be borne in mind by British botanists; the subscription for membership is only three shillings.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Mr. R. H. Yapp, of Cambridge, has been appointed professor of botany in the University College of Aberystwyth in succession to Prof. J. H. Salter.

Mr. Hugh Davies has been appointed head of the building trades department of the Northern Polytechnic Institute in succession to Mr. H. W. Richards, who was recently made principal of the London County Council School of Building at Brixton.

The debt of 5000*l.* in connection with the University College, Bristol, has now been entirely liquidated. Sir William H. Wills, Bart., and Sir Frederick Wills, Bart., M.P., each contributed 1000*l.* towards the amount required, and a further sum of 500*l.* has been given by the managers of the Exhibition of Welsh Industries recently held in Bristol.

The governing body of the South-western Polytechnic, Chelsea, has accepted with very great regret the resignation of the principal, Mr. Herbert Tomlinson, F.R.S. At a meeting held on December 16, the following resolution was passed:—"That the governing body hereby desire to record their cordial appreciation of the admirable work that Mr. Tomlinson as the first principal has accomplished in organising and developing the institute in all its branches."

At the Royal United Service Institution Mr. C. E. Stromeyer read a paper on short service training for reserve officers. It contained a sketch of the German "Einjährig Freiwilliger" system, which, according to the author's views, supplements the ordinary school and university studies by a good insight into the human nature of the German workman by bringing him and the one year volunteer into close contact while serving together in the ranks. German technical students are therefore fit at an early age for the posts of submanagers in industrial undertakings, whereas English lads fresh from technical colleges are not trusted to deal with workmen. The author suggests that the War Office should encourage young men from public schools and from universities to join the army for a short period.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, December 21.—M. Albert Gaudry in the chair.—After the delivery of the annual presidential address, the prizes offered for the year 1903 were awarded. In geometry, the Francœur prize to M. Émile **Lemoine** for the whole of his work in geometry; the Poncelet prize to Prof. M. **Hilbert,** University of Göttingen, for his works on the principles of geometry. In mechanics, the extraordinary prize of 6000 francs was divided as follows:—one-half to M. **Maugas,** chief engineer in the navy, for his researches on the stability of battleships and his works on submarine navigation; the other half was divided in equal parts between Lieutenants **Jehenne, Gaillard,** and **Germain,** the first for his work in the application of wireless telegraphy to the navy, the other two for the improvements they have carried out in apparatus intended for the transmission of orders or signals during a battle. The Montyon prize was awarded to Prof. **Bodin** for designing and executing a new system of cantilever at the Viaur viaduct; the Plumey prize to Prof. **Marchis** for the free courses of instruction in applied mechanics organised by him, and more especially for his lessons on steam and heat engines. The Fourneyron prize was not awarded. In astronomy, the Pierre Guzman prize was not awarded; the Lalande prize was awarded to Prof. **Campbell,** of the Lick Observatory, for his investigations in stellar spectroscopy and astronomical physics; the Valz prize to M. **Borrelly** for his discoveries of comets; and the G. de Pontécoulant prize, intended to encourage researches in celestial mechanics, to M H. **Andoyer** for his memoirs on the theory of the moon and that of the small planets. In physics, the Hébert prize was awarded to Dr. E. **Goldstein,** of the Berlin Observatory, for his investigations, during thirty years, of electric discharges through rarefied gases and the discovery of a particular kind of radiation; the Hughes prize fell to M. Pierre **Picard** for the improvements effected in telegraphy, improvements which have increased the rapidity of transmission in submarine cables; the Gaston Planté prize to M. **Hospitalier** for his ondograph. In statistics, the Montyon prize was not awarded, though MM. **Loncq,** de Montessus **de Ballore,** and **Razous** each received an honourable mention. In chemistry, the Jecker prize was given to M. L. **Bouveault** for his numerous researches in organic chemistry during the last seventeen years. The La Caze prize fell to M. A. **Guntz** for his thermochemical investigations on the compounds of fluorine with metalloids and with metals. In mineralogy and geology the Delesse prize is awarded to M. Emmanuel **de Margerie,** joint author with General de la Noë of "Les Formes du Terrain," and translator into French of "La Face de la Terre," by Prof. Suess, of Vienna. In physical geography, M. R. P. **Colin** received the Gay prize for the determination of numerous geographical positions in Madagascar. In botany, the grand prize of the physical sciences was not awarded, nor were the Bordin and Desmazières prizes. M. **Maire** was accorded the Montagne prize for his delicate researches in connection with the Basidiomycetes. The Thore prize was awarded to M. **de Istvanffi** for his work upon the diseases of the vine known as "white" or "red" rot. In rural economy the Bigot de Morogues prize fell to M. Eugène **Rister** for his well-known "Géologie agricole." In anatomy and zoology, M. R. **Fourtau** is accorded the Savigny prize for his memoirs on Egyptian stratigraphy and other palæontological subjects, and M. **Krempf** receives an honourable mention. The Countess **Maria von Linden** gained the Da Gama Machado prize for two memoirs on the development of the colours in the wings of butterflies. In medicine and surgery, Montyon prizes are awarded to M. **Dominici** for his memoirs on the normal condition of certain organs, and also when infected; to

M. Jean **Camus** for a work entitled "Les Hémoglobinuries"; to M. Robert **Lœwy** for his method of peritoneal grafting. Honourable mention was also made of the contributions of MM. **Nicolle** and **Remlinger, Nobecourt, Merklen** and **Sevin**, Ch. **Monod** and J. **Vanverts.** The Barbier prize is divided between MM. **Anthony** and **Glover**, the work of the former being in connection with the sternum, and that of the latter a new therapeutic method based on the application of a warm spray of non-volatile liquid. The arrears of the Bréant prize were divided between M. E. **Chambon** for his memoir "L'Institut de vaccine animale, son histoire depuis sa fondation en 1864," and Dr. **Borrel** for his papers on the parasitic theory of cancer. The Godard prize was awarded to Drs. N. **Hallé** and B. **Mötz** for their contributions to the pathological anatomy of the bladder. Dr. J. B. **Hillairet** received an honourable mention. The Lallemand prize was divided between Mlle. **Joteyko** and MM. **Garnier** and **Cololiau**, and Dr. Giuseppe **Pagano** was honourably mentioned. Dr. Paul **Godin** received the Larrey prize for his contribution on military hygiene, and M. G.-H. **Lemoine** and Dr. Jules **Régnault** were honourably mentioned. Dr. F. **Battesti** was accorded the Bellion prize, while Dr. R. **Glatard** was mentioned very honourably. The arrears of the Mège prize fell to Dr. A. **Monprofit** for his work "Chirurgie des ovaires et des trompes." Dr. Alfred **Fournier** was awarded the Chaussier prize for his important contributions to medical and social science. In physiology, the Montyon prize was divided between M. **Arthus** for his researches on the coagulation of the blood, and M. V. **Henri** for his work on the action of diastases. The work of M. **Bounhiol** on the respiration of annelids receives particular mention. The Philipeaux prize was accorded to M. Lucien **Daniel** for his investigations as to the nature of grafts and grafting. Prof. Chas. **Richet** received the La Caze prize for his numerous contributions to physiology. Dr. J. **Denoyès** was awarded the Pourat prize for his treatment of the subject proposed, viz. the action of high frequency currents on the phenomena of life. The essays of MM. **Regnier** and **Bruhat** were honourably mentioned. Prof. H.-G. **Zeuthen**, of Copenhagen, received the Binoux prize for his studies on the history of the sciences. Of the general prizes, the Lavoisier medal was awarded to Prof. Carl **Graebe**, of Geneva, for his work in organic chemistry. Berthelot medals were awarded to Prof. **Graebe** and to MM. **Bouveault, Guntz, Chavanne,** Victor **Henri, Arthus,** and **Capelle.** The Montyon prize (unhealthy trades) was not awarded, but an honourable mention was accorded to M. Edouard **Capelle** for his work on lighting and heating by acetylene, the Wilde prize to M. **Collet** for his determinations of the intensity of gravity, the Tchihatchef prize to Dr. Sven **Hedin** for his explorations in Asia, the Cuvier prize to M. Eugène **Simon** for his "Histoire naturelle des Araignées," the Parkin prize to MM. **Lacroix** and **Giraud** for their investigations on the recent eruptions of Martinique, the Petit D'Ormoy prize (mathematical sciences) to M. Jacques **Hadamard**, the Petit D'Ormoy prize (natural sciences) to M. Bernard **Renault,** the Boileau prize to M. Marius-Georges **Grandjean**, the Estrade-Delcros prize to M. Léon Teisserenc **de Bort** for his fourteen years' work in meteorology, the Cahours prize between MM. **Marquis** and **Chavanne,** the Saintour prize to M. Marcel **Brillouin** for his works on mathematical physics, the Trémont prize to M. Charles **Frémont** for his method of determining the limit of elasticity of metals employed in the arts, the Gegner prize to M. Jean-Henri **Fabre** for his investigations in biological science, the Lannelongue prize to Mme. Ve **Nepveu,** the prize founded by Mme. la Marquise de Laplace to M. **Rémy** (Louis-Gabriel), and that founded by M. Félix Rivot is divided between MM. **Rémy, Breynaert, Gillier,** and **Bouteloup.**

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part v., 1903, contains the following memoirs communicated to the Society:—

July 25.—K. **Schwarzschild**: Electrodynamics, iii. On the motion of the electron. A. **Schœnflies** and F. **Pockels**: Report on Plücker's scientific remains.

August 5.—P. **Furtwangler**: On the construction of the *Klassenkörper* for given algebraical domains, which contain the *l*th root of unity.

October 31.—F. **Bernstein**: On the *Klassenkörper* of an algebraical domain (second paper). L. **Heffter**: Proof of the Cauchy-Goursat integral theorem. R. **Schimmack**: On the axiomatic basis of vector-addition. C. **Runge**: On the electromagnetic mass of the electrons. R. **Fricke**: On the polygonal *continua* occurring in the theory of automorphous functions.

DIARY OF SOCIETIES.

THURSDAY, DECEMBER 31.

ROYAL INSTITUTION, at 3.—Extinct Animals: Prof. Ray Lankester, F.R.S.

FRIDAY, JANUARY 1.

GEOLOGISTS' ASSOCIATION, at 8.—The Jurassic Rocks of East Greenland: Dr. Victor Madsen, translated with additional observations by Miss Ethel G. Skeat.

SATURDAY, JANUARY 2.

ROYAL INSTITUTION, at 3.—Extinct Animals: Prof. Ray Lankester, F.R.S.

MONDAY, JANUARY 4.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—On the Defects of Uncarburetted Water Gas as Fuel for Laboratory Use: Dr Chikashigé.—The Rapid Estimation of Mercury by means of Hypophosphorous Acid: B. F. Howard.—The Determination of Moisture in Nitro-glycerine Explosives: Arthur Marshall.

ARISTOTELIAN SOCIETY, at 8.—Prof. Sidgwick's Ethical Philosophy: Miss E. E. Constance Jones.

TUESDAY, JANUARY 5.

ROYAL INSTITUTION, at 3.—Extinct Animals: Prof. Ray Lankester, F.R.S.

WEDNESDAY, JANUARY 6.

SOCIETY OF ARTS, at 5.—Navigation of the Air (Juvenile Lecture): Eric S. Bruce.

GEOLOGICAL SOCIETY, at 8.—On a Palæolithic Floor at Prah Sands in Cornwall: Clement Reid, F.R.S., and Mrs. Clement Reid.—Implementiferous Sections at Wolvercote (Oxfordshire): Alexander M. Bell.

THURSDAY, JANUARY 7.

RÖNTGEN SOCIETY, at 8.30.—The Revelations of Radium: Dr. G. B. Batten.

ROYAL INSTITUTION, at 3.—Extinct Animals: Prof. Ray Lankester, F.R.S.

FRIDAY, JANUARY 8.

ROYAL ASTRONOMICAL SOCIETY, at 5.

SATURDAY, JANUARY 9.

THE CRITICAL STATE.

Le Point critique des Corps purs. Pp. viii + 255. (Paris: C. Naud, 1904.)

OF late numerous attacks have been made on the commonly accepted theories relating to the conditions which obtain at the critical temperature of pure substances, and though the assailants may have received little support, or even attention, from the mass of their physical brethren, it is time that certain questions relating to the critical state were more definitely settled.

In the opening chapter of this work the author discusses the general case of the evaporation of liquids at temperatures up to their critical point, leading up to the statement, which opens the second chapter, that the theories of Andrews and Van der Waals are insufficient to explain the observed phenomena. For instance, Battelli has attempted to prove that the temperature at which the meniscus disappears in a sealed tube containing alcohol is a function of the concentration of the alcohol in the tube. The experimental results are quoted; they are as follows:—

Date of experiment	Mean density of liquid and vapour in sealed tube	Observed critical temperature
1891	0·3195	236·39
1892	0·3434	237·02
1891	0·3448	236·26
1891	0·3839	235·66
1891	0·3889	235·94
1892	0·4000	236·43

Similar results were obtained in the case of ether, but it is difficult to see how they may be fairly interpreted as supporting the author's views. A very small quantity of impurity would be quite sufficient to account for these abnormal, but by no means concordant results.

The experiments of Galitzin are next quoted to prove that the temperature of disappearance and reappearance of the meniscus is dependent not only on the mean density of the substance in the tube, but also on the dimensions of the latter. Sealed tubes containing ether were heated slowly to 200° C., maintained at that temperature for twenty minutes, and then allowed to cool slowly. A maximum difference of 0.9° C. between the temperatures at which the meniscus disappeared and reappeared again was observed, and as no evidence to the contrary is forthcoming, there is no reason for assuming that the temperature difference is not due to the lagging of the temperature of the liquid in the capillary tube after that of the bath. It is further remarked that, if one repeatedly heats and cools such a tube, the meniscus tends to reappear after each operation at a lower point in the tube. That this is not observed when the tube is shaken is highly significant.

In the succeeding chapters the various methods which have been applied to the determination of the critical constants are described and criticised, theoretical questions being discussed as they occur. Opening with an account of Andrews's experiments, and the development of his method at the hands of Ramsay, Young, and others, the author leads up to a discussion on the application of the modified gas equation to the calculation of the critical constants from the data for the isothermals. As an example, he takes Sarrau's attempt to employ Clausius's equation to calculate the critical constants of hydrogen from Amagat's determinations of the compressibility of that gas. The results are, of course, wide of the mark, but it is interesting to note that Wroblewski, who investigated the isothermals of hydrogen between +100° C. and −182° C., obtained, by means of a similar equation, a very fair approximation of their values.

In chapter vi. the author discusses the effect of the gravity of the substance under investigation on the density at different levels in the capillary tube. Here again our knowledge of the subject is very scanty, and experimental evidence is required to support the theoretical results of Gouy and others who have treated the subject mathematically.

Particularly interesting accounts of special series of researches are given in the succeeding chapters. Olszewski's determination of the critical pressure of ethylene, oxygen, and hydrogen is described in detail, and the theory of the method, which is not dealt with in the original paper, is explained by means of a diagram. This piece of work is important, as it involves a new method for the determination of critical pressures, and gives us the only published experimental data for the critical pressure of hydrogen. Some of the methods described by the author as "élégantes mais pur précises" are interesting, as they furnish suggestions which may be applied to other problems. The behaviour of mixtures, which could not be entirely omitted from the work, is briefly discussed, and diagrams are given illustrating the graphical method of treating the results. A table of critical constants occupies several pages.

The final section of the book deals with the theories which have been put forward to account for the apparent irregularities in the behaviour of pure substances, and the deviation from the simple laws hitherto supposed to govern the phenomena which take place at the critical point. The existence of two kinds of molecules, gasogenic and liquidogenic, which persist in the vapour phase, was first suggested by de Heen, and has recently received support from Traube and others. As was long ago pointed out by Sir G. Stokes, de Heen's theory demands that the pressure of a saturated vapour of a pure substance, like that of a mixture, must be dependent on the relative masses of the liquid and vapour phases, and this is contrary to all experience. Modifications of this theory, involving an idea of a definite equilibrium dependent only on temperature between the two kinds of molecules, may be more easily tenable; but, as the author suggests, the existence of liquidogenic molecules, having only a transitory existence in the vapour phase, and dissociating slowly into gasogenic molecules, would account for most of the phenomena which have been observed.

There are two obvious sources of error in measure-

ments of the kind described in this work. In the first place the substances must be of a very high degree of purity, and as the author justly remarks, there is usually no evidence that this has been the case. In the second, the difficulties experienced in maintaining temperatures which do vary at a greater rate than 0.002° per minute are enormous, and in dealing with substances enclosed in thick-walled capillary tubes, the temperature difference might be in some cases of the same order as the observed abnormalities were the temperature less steady.

Whatever may be the fate of the new theories or the opinion as to the value of some of the experiments on which they are based, we are indebted to the author for collecting and arranging this mass of information, and for bringing the points at issue so clearly before the scientific world. M. W. T.

THE B.M. HAND-LIST OF BIRDS AND CATALOGUE OF EGGS.

A Hand-List of the Genera and Species of Birds. Vol. iv. By R. B. Sharpe. Pp. xii+391. (London: Printed by Order of the Trustees, 1903.)

Catalogue of the Collection of Birds' Eggs in the British Museum (Nat. Hist.) Vol. iii. By E. W. Oates and S. G. Reid. Pp. x+349; 10 plates. (London: Printed by Order of the Trustees, 1903.)

WHEN the publication of the valuable "Hand-List" was commenced, it was considered that the work would be completed in four volumes. The fourth volume is, however, before us, and the author's task is far from being ended. This, as stated in the preface by the director of the Museum, is due to the unexpectedly large amount of space occupied by the Passeres (or Passeriformes, as the author prefers to call them), the number of named species of which group has been largely augmented during the progress of the work. Accordingly, in order to keep the present one of moderate dimensions, it has been decided to complete the work in five, in place of four, volumes. The fifth and concluding volume, it is satisfactory to learn, is in a forward state, and will probably be issued shortly.

Our opinion of the high value of this work having been already expressed in our notices of the earlier volumes, it need not be repeated here, although we must again state that it would have been an improvement had the dates of publication of the generic names been introduced. We are, moreover, debarred from criticising the right of certain forms and groups to specific or generic rank, for the author in this instance has been bound to follow the arrangement adopted in the "Catalogues."

All that remains open to us in the way of criticism is in relation to geographical and topographical names, and even here there is not much with which to find fault. We venture to think, however, that the author uses the term "Himalayas" or "Himalaya Mountains" in somewhat too wide a sense. Possibly he may be justified in including Kashmir in the "Himalayas," although scarcely in the "Himalaya Mountains," but there is no justification for calling Ladak (p. 147) a part of that system. Then, again, on p. 149 we find Murree (Murri) described as being in the *eastern* Himalaya. The author's spelling of that name—as Murri—is, moreover, without justification. Many years ago the Indian Government decreed that the names of well-known places were to be spelt in the old-fashioned way. If this ruling be followed, Murree is the proper orthography; if, however, the Hunterian system be followed, it should be Mari; Dr. Sharpe's "Murri" is neither one system nor the other.

If the proof-reading had been done a little more carefully, certain discrepancies in the printing of names might also have been avoided. We should not have had, for instance, in one place Amur-land (p. 138) and in another Amurland (p. 339), or Somali Land (p. 12) and Somali-land (p. 293), or Szechuen (p. 8) and Sze-chuen (p. 322), or Damara Land (p. 22) and Damara-land (p. 331). Again, we believe that Gansu (p. 321) and Kansu (p. 323) are one and the same. Finally, we do not like the phrase (p. 259) "Arctic and Subarctic regions of both hemispheres," which, although no doubt etymologically correct, sounds somewhat ambiguous.

In regard to the third volume of the "Catalogue of Birds' Eggs," the most notable feature is its dual authorship, or, to be precise, that it is written by Mr. E. W. Oates, assisted by Captain Savile Reid. The explanation of this is to be found in the preface, where it is stated that, owing to the ill-health of Mr. Oates, it had been found necessary to entrust the completion of the work to other hands. In the case of this volume the MS. was left in a forward state by Mr. Oates, and has been revised, together with the proofs, by Captain Reid, who has also incorporated in the text references to recently acquired specimens.

The present volume commences with the parrots, and includes the whole of the so-called "picarian" birds, together with a considerable number of the passerines, that is to say, from the Pteroptochidæ and Formicariidæ to the bulbuls (Pycnonotidæ). From what has been written above, it is scarcely necessary to add that the plan followed in this volume is the same as in its predecessors. Now that a change of authorship has taken place, we may suggest that the value of the work would be decidedly increased if the characteristics of the eggs of the different families and genera were given in some detail in the volume yet to come. As it is, no regular rule seems to have been followed in this respect, and it is therefore quite impossible to gather of what value are egg-characters in classification.

The exquisite plates illustrating this volume are, like those in its predecessors, reproduced from sketches by Mr. H. Gronvöld. Although the number of the plates is somewhat less than in vol. ii., the number of eggs figured is (owing to their smaller size) much greater. It may be added that small eggs, like those figured in this volume, form much more attractive octavo plates than is the case with the larger ones depicted in the earlier volumes, and whichever of the two authors is responsible for the grouping of the specimens figured he is to be congratulated, from an artistic point of view, on the result. As a rule, eggs

which have not previously been figured are selected for illustration.

The total number of species catalogued in this volume is 907, and the number of eggs 8474; the latter are, however, very unevenly distributed among the various species, of many of which there is but a single egg in the collection. This is the case, for instance, with three out of the four species of "frog-mouths" catalogued, and likewise with many of the kingfishers, cuckoos, and humming-birds.

The collection is especially rich in eggs of the common cuckoo, associated in a large number of cases with the clutches laid by their involuntary foster-parents. After remarking on their variability in size, the authors state that the cuckoo's eggs likewise present a considerable range of diversity in colour and the character of the marking, although the great majority approach in these respects to the eggs of the meadow-pipit and skylark. Eggs of this type constitute the great bulk of the series in the collection. Some, however, like those associated with the eggs of *Ruticilla phoenicurus*, are blue, while one closely resembles that of a chaffinch. Curiously enough, cuckoos' eggs from hedge-sparrows' nests are of the ordinary type, and show no tendency to become blue. Altogether, the collection includes cuckoos' eggs taken from no less than forty-one different species of birds, ranging in size from a shrike to a fire-crest.

Did space permit, many other interesting points connected with öology might be mentioned; as it is, we must bring our remarks to a close with the expression of our opinion of the great interest of this unique work. R. L.

MODERN SCIENCE POPULARISED.

New Conceptions in Science. By Carl Snyder. Pp. xii+362. (London and New York: Harper and Brothers, 1903.) Price 7*s.* 6*d.* net.

IN the absence of any preface, it is necessary for the reader to form his own opinions as to the aim or object of the book considered as a whole. This, evidently, is to arouse an interest in scientific work among unscientific people by telling the story of the discoveries of the day in unscientific language. We have here portraits of the man that weighed the crown of King Hiero, of the man that broke the atom into ions, of the man that caught and fought the deadly microbe, and other pioneers of science introduced in terms somewhat suggestive of those we have used above. Several of the illustrations show the discoverers at work in their own laboratories, and remind us that this book hails from the same land which in recent years has flooded our breakfast tables with portraits of literary men writing articles by the side of revolving bookcases.

We have spoken of the book as being written in unscientific language, but it would be better to describe the language as unconventional, unorthodox, and very funny to an English mind. As instances, we may quote "chips of atoms" as applied to corpuscles; Marconi is described as having "since the Salisbury Plain trials with kites, taken to the water wholly," and, later on, it is said of him, "Then the tireless experimenter looked out over waste seas, saw in fancy the foggy banks of Newfoundland and said confidently 'That's the next.'" Again, "The Hertz-waves have had a sort of Messianic history. They had been foretold." "This scale" (speaking of Centigrade) "is in universal use throughout the world save in two backward countries called England and the United States." (The author forgets that there are certain enlightened countries which still use Réaumur's scale.) "If like this mechanical eye our eyes were sensitive to these electrical waves, then we might watch the progress of a play in Buenos Ayres or have witnessed the struggles at Peking." "Those who were reared to the ideas of Clerk Maxwell, regarding electricity as a wave and wobble in the highly hypothetical ether, have not failed to implant upon the new theory their collective feet." Light and other waves are stated to "clip through space at 184,000 miles per second." "If, as Prof. Dolbear picturesquely remarks, we could some way get a 'kick' on the ether, space navigation would be easy. It does not seem impossible that we shall be able to do this within another hundred or two hundred years."

The book is not confined to physical science alone. It contains a chapter on Prof. Loeb's discovery of artificial parthenogenesis, another on the nature of life, in which is suggested the possibility of reversing the life processes and growing backward, and a chapter headed "The Spirit Rappers, the Telepaths and the Galvanometer." Seriously speaking, the most important chapter is undoubtedly that dealing with "America's Inferior Position in the Scientific World." In it, among other points, the author urges the necessity of founding an institution like our Royal Institution in America, and directs the attention of his fellow countrymen to their general backwardness in research. We over here are apt to think of the American man of science as being pretty well off in view of the large number of universities existing in the United States, and the large number of chairs attached to each of them, which should result in the individual professors having far more time for research work than they have in this country. If, however, the author succeeds in impressing on his fellow countrymen the need of devoting further endowments for the furtherance of research work pure and simple, the book will not have been written in vain. The danger is that the important part played in science by long formulæ involving *dx*'s and *dy*'s, inverted deltas and signs of integration will be overlooked. G. H. B.

APPLIED PSYCHOLOGY.

Outlines of Psychology: an Elementary Treatise with some Practical Applications. By Josiah Royce, Ph.D., LL.D., Professor of the History of Philosophy in Harvard University. Pp. xxvii + 392. (New York: the Macmillan Company; London: Macmillan and Co., Ltd., 1903.) Price 4*s.* 6*d.* net.

THE number of persons who are anxious to study psychology in order to make themselves more efficient as teachers is already large, and is happily

increasing very rapidly. This book is designed to introduce them to the study of the subject, and may be warmly recommended to them, but it is worthy of the attention of the professional psychologist also. The special features of the book are the freshness and clearness of the treatment, and the novel arrangement of mental phenomena under the three heads sensitiveness, docility, and initiative. Prof. Royce thus ignores the traditional divisions of the subject, which, though merely survivals from the old and misleading faculty-psychology, have largely determined the mode of treatment of most modern writers. By so doing he is enabled to treat every mental process as a whole having cognitive, conative and affective aspects.

Though not himself an experimenter or a physiologist, Prof. Royce fully and generously admits the importance of physiological and experimental psychology, and recognises that the advance of the subject represented by this book is largely due to modern work by those methods; his sketch of the functions of the nervous system and his numerous references to physiological considerations are altogether admirable and judicious, and he shows how greatly experimental methods have furthered our analysis of mental processes.

Here and there throughout the chapters practical deductions of the first importance to teachers are clearly and soundly drawn; for example, it is admirably shown how "differentiation of the simultaneous slowly results from the repeated acts, and from the powers of discrimination which have been cultivated in connection with them," and there follows the maxim, "Undertake to systematise this differentiation of consciousness through fitting series of successive deeds."

One of the most novel features is the treatment of the feelings. While agreeing with Wundt in regarding the classification of feelings into the two groups, pleasant and unpleasant, as very inadequate, Prof. Royce does not accept that author's six classes, but regards feelings of quiescence and of restfulness as two classes of antagonistic feelings correlative with the pleasant and unpleasant. In the chapter on the conditions of mental initiative, the importance of this distinction is fully illustrated. It is there forcibly shown how "mental initiative" depends upon "a certain overwealth of persistent activities" not immediately adaptive and not necessarily pleasant, and it is asserted that "all such activities are characterised by the feeling of restlessness. In their physical aspects they are examples of the 'tropisms' of Loeb." This last statement is difficult to accept. In the introduction Prof. Royce shows that he has been much impressed by the phenomena of "tropism" as manifested by lowly organisms, and he seems to feel that the conception of the "tropism" is of great importance for psychology. But the later references to the subject do little to justify the expectations thus aroused. In the case of the "overwealth of persistent activities" which are so important for mental growth, it would seem to be truer to say that they are examples of "irritability," the fundamental property of all living substance, and to treat them as examples of "tropisms" is not warranted by any considerations advanced in the book or known to the present writer.

The concluding chapters deal with varieties and abnormalities of minds, and many valuable hints are given as to the special treatment of individuals demanded of the teacher and parent. Among all the many books on psychology, there is none that within so small a compass, can give more insight into the life of the mind, and none that can be studied by schoolmasters with greater or equal advantage to their professional efficiency. W. McD.

OUR BOOK SHELF.

Animal Studies: a Text-book of Elementary Zoology for Use in High Schools and Colleges. By David Starr Jordan, V. L. Kellogg, and Harold Heath, of Leland Stanford Jr. University. Pp. 459; 259 figures. (New York and London: Appleton and Co., 1903.) Price 5*s*. net.

THIS is an interesting and delightful text-book of elementary zoology, combining some parts of "Animal Life" and "Animal Forms," in the same series, with new material on classification, extinct forms, geographical distribution, special adaptations, instincts, and economic value. Beginning with chapters on the conditions of animal life and the principles of classification, the volume takes a survey of the most important classes from Protozoa to mammals. Then follow chapters on life-histories, the struggle for existence, adaptations, animal communities, commensalism and parasitism, protective resemblances and mimicry, the special senses, instinct and reason, and so on. When we compare a school-book on geography of a quarter of a century ago with the best modern school geography, we seem to breathe a different atmosphere, and so it is when we compare the natural history for schools which was in circulation twenty-five years ago with this lively, up-to-date, well thought-out, beautifully illustrated, and, in short, well adapted modern school text-book of zoology.

We quote, in illustration of its educational value, one example:—"At one time we had two adult monkeys, 'Bob' and 'Jocko,' belonging to the genus Macacus, neither with the egg-eating instinct, and a baby monkey, 'Mono,' of the genus Cercopithecus, whose inherited impulses bore a distinct relation to feeding on eggs, just as the heredity of Macacus taught the others how to crack nuts or to peel fruit. To each of these monkeys we gave an egg, the first that any of them had ever seen." The result of the experiment was in the highest degree instructive. Mono cracked the egg against his upper teeth, made a hole in it, and sucked it. "Then holding the egg-shell up to the light and seeing that there was no longer anything in it, he threw it away." He treated all subsequent eggs in the same expert fashion, while "Bob" and "Jocko" treated their eggs like nuts, and therefore ineffectively.

We recommend this book strongly; it is simple but not superficial, it is both interesting and instructive; it is written with an educational perspective. It is particularly desirable in elementary books that every general statement should be critically scrutinised, and the standard of accuracy in this volume is a high one. We are not, however, prepared to accept every statement, *e.g.* that fur-seals "absorb the water needed through pores in the skin." J. A. T.

Das Zeisswerk und die Carl-Zeiss-Stiftung in Jena. Ihre wissenschaftliche, technische und soziale Entwickelung und Bedeutung, für weitere Kreise dargestellt von Felix Auerbach (Prof. a.d. Universität). Pp. vi+124. (Jena: Gustav Fischer, 1903.)

This short popular account of the optical works in Jena will be of interest to a wide circle of readers. Of the successful application of science to industry no more striking illustration can be found than in the history of the Zeiss firm, with its aim of "scientific exactness and perfection of workmanship," while to many the description of the present organisation of the undertaking, and the socialistic features of the charter under which it is now controlled, will no less appeal.

The early efforts of Carl Zeiss towards the improvement of the microscope, his adoption of Abbe as scientific partner, and the revolution in the optical theory of the instrument due to Abbe's work, are dealt with in some detail. The need, emphasised by Abbe's investigations, of greater variety in the character of optical glass, to render possible the removal of the chief defects of lens systems, led to the foundation, in 1884, of the glass works of Otto Schott, and from this year we may date an enormous advance in the construction of optical instruments, with a further development of the Jena industry. This brings us to an account of the existing organisation, and a description of the main departments, with details and illustrations of many of the most important and best known instruments, as well as of the workshops and buildings.

The latter part of the work deals with the social and socialistic aspects of the present system of administration. In 1891, some four years after the death of Carl Zeiss, Abbe devised his rights of property in the optical and glass works to the undertaking itself, and originated the statute, under which, after receiving in 1896 the legal sanction of the Duke of Saxony, the "Carl-Zeiss-Stiftung" is now controlled. Particulars are given of the statutory standing of the employés, the system of profit-sharing, the regulation of hours of work, the pension scheme, as well as of institutions founded for the benefit of the workmen, and benefactions to the university and to the town.

In addition to Carl Zeiss and Abbe other personalities connected with the undertaking, Schott, Czapski, Straubel, Pulfrich, &c., are briefly characterised, and with these names may be also mentioned that of the old foreman, August Löber, to whom the firm is indebted for many improvements in technical detail.

Reasons Against the Theory of Evolution. By Thomas Woods, M.D., M.R.C.S.I., L.R.C.S.I., &c. Pp. viii+52. (London: W. R. Russell and Co., n.d.)

The author of this booklet may have perfectly definite convictions as to the truth or falsity of the theory of evolution, but he has hardly succeeded in making his attitude towards the doctrine clear to his readers. His object, the preface informs us, is to notice some occurrences, said to be due to evolution, the contrivances for which must have been pre-arranged, and therefore could not have been the result of accidental circumstances. "If," he proceeds, "Evolution results from 'circumstances and surroundings,' pre-arrangement, of course, cannot have occurred, and if it can be shown that such pre-arrangement has in *any* instance taken place the whole thing must fall." This can only mean that the author considers himself in a position to disprove the existence of evolution *in toto*. But, on the other hand, we read that "if we regard Evolution as *one* of the means made use of, . . . we may not err." We do not see how these statements are to be reconciled.

Considering, however, the title of the essay, and the whole tone of the author's remarks, we shall probably be doing him no injustice if we put him down as a root and branch opponent of the theory as commonly understood. His leading argument appears to be this:—facts such as the grouping of the planets of the solar system, the freezing and boiling points of water, and, in the organic world, the provision made by nature for the welfare of unborn offspring, with other similar conditions, seem to stand in definite relation with the existence of life on the earth; these conditions must have been pre-arranged, and therefore evolution is impossible. It is scarcely necessary to point out that the argument is a *non sequitur*. In estimating the evidence for and against evolution, it is absolutely immaterial to inquire whether the conditions under which it is supposed to have taken place are or are not the result of "pre-arrangement." Dr. Woods claims in an appendix to have anticipated Favre and Silberman in laying the foundations of thermochemistry. It is unfortunate that in entering the lists of biological controversy he has omitted to acquaint himself with the elementary conditions of the evolutionary problem.

Lessons in Physics. By Lothrop D. Higgins, Ph.B. Pp. vii+379; with plates and diagrams. (Boston, U.S.A., and London: Ginn and Co., 1903.) Price 4s. 6d.

It is rather difficult to "place" this book. At the end there is a glossary in which (amongst more difficult ones) words are defined such as these: absorb (to take in), alter (to change), constant (always the same), detect (to find out), enlarge (to make larger) Apparently, then, the pupil is not expected to be certain about words of two syllables. We, accordingly, look for great simplicity in the text, especially as the author in his preface trusts that the explanations "have been made with a care which should render them unusually clear and simple." We open the book at random at the first section on magnets, and find the following definition as the first sentence:—"A Magnet is a body so acted upon electrically that it has the power to exert magnetic force."

We open on p. 319, and we find Ohm's law based upon the relative values of E.M.F. and current in the primary and secondary of an induction coil.

We open again at p. 250, and learn, in explanation of the rainbow, that "the sunlight passes through some thin clouds whose particles of water refract the rays, and the spectrum is formed on other clouds or reflected to the eye."

The first 120 pages, on mechanics, appear to be the best part of the book. There are several remarkably pretty plates.

The Certainty of a Future Life in Mars. Being the Posthumous Papers of Bradford Torrey Dodd. Edited by L. P. Gratacap. Pp. iv+266. (New York: Brentano's, 1903.)

The planet Mars has been the subject for many works of fiction, and in the present volume we have another addition to the list.

The main idea of the train of thought in these pages is that upon each planet the possibilities of development just attain to the margin of the next higher step in mental evolution. Thus in Venus the period of *sense* develops to the possibility of the period of *science*, but does not attain it. On the earth the period of *science* develops to that of *spirit*, while the latter is only reached in the planet Mars. On this assumption souls of different degrees move from planet to planet.

The chief characters in this story are Mr. Dodd, his wife and son (the author of these papers). The father and son work out a system of wireless telegraphy, and

after the death of the former, whose soul is transported to Mars, they get into communication with each other.

The posthumous papers consist of the record left by the son, who describes all their experiments, hopes, failures, successes, and, lastly, the extra-planetary wireless messages he received.

Those interested in this class of fiction can spend a pleasant hour or two over these pages.

On the Lakes of South-eastern Wisconsin. By Prof. N. M. Fenneman. *Bulletin* viii. of Wisconsin Geol. and Nat. History Survey. Pp. xv+178. (Madison, Wisconsin: Published by the State, 1902.)

The preface and the introduction announce the object of this work. It is intended as a guide to the teacher of geology, and shows how the shores of these lakes may form beautiful illustrations of the principles of wave, current, and ice action. The first chapter gives a general account of the origin of such lakes, and the second is devoted to a general and more or less theoretical discussion of the geological agents at work. After this the lakes are taken up one by one, and it is shown how the various features of the shore have arisen. There are many very good and aptly chosen photographs, which bring out clearly the points mentioned in the text, and make the book interesting even to those who cannot see the lakes for themselves.

Most of the book is devoted to the features of the shores, but it is also shown how the hydrographic maps may be used to decipher the origin of the basins, and in the case of Lake Mendota there is an interesting discussion of the results obtained by dredging, which are said to indicate currents below the wave-base. The unpublished work of the director of the Survey, Dr. Birge, on the temperature of these lakes is also said to confirm these conclusions. We shall look forward to the publication of these temperature observations. E. R. W.

Malessere Agrario ed Alimentare in Italia. By Italo Giglioli, Direttore della R. Stazione Agraria di Roma, &c. Pp. lxxxii+707. (Portici, 1903.)

In this work Prof. Giglioli has attempted a detailed survey of the agricultural state of Italy in comparison with other nations. He considers one by one the various branches of the industry, the production of wheat, maize, rice and other cereals, wine, fruit, olives and silk, eggs, butter, cheese and the many minor branches of rural activity which are possible in the climate of Italy. In each case a comparison is drawn between the conditions of the past and those which prevail to-day both in Italy and the chief competing countries. Both as an ardent patriot and a man of science, Prof. Giglioli is troubled by the increasing poverty of the rural districts as compared with the towns, especially when one travels out of the favoured northern provinces of Lombardy and Tuscany into middle and southern Italy. He indicates how the actual production of the land is declining, so that Italy with all its traditional farming skill and with the vast possibilities of its climate is coming to be more and more dependent upon other nations for food which could be grown within its own borders if only more intensive methods of cultivation were resorted to. Aggravated as the case is in parts of Italy by the poverty of the people and their entire dependence upon agriculture, the problem is one which all the west European States are being called upon to face; how can agriculture, which is a primitive industry, live in a highly civilised State against the competition of the great areas of virgin soil like Argentina or the North-West? To English economists who want an enlightened and temperate review of the situation in a nation not unlike our own we commend Prof. Giglioli's book.

LETTERS TO THE EDITOR.

Does the Radio-activity of Radium depend upon its Concentration?

Some experiments have recently been made to test whether the radio-activity of radium is influenced by the continuous bombardment to which it is subjected by its own radiations. In an article in this Journal on radium (April 30, 1903) Prof. J. J. Thomson suggested that the radio-activity of radium may possibly depend upon its degree of concentration, and that a given quantity of radium, diffused throughout a mass of pitchblende, may be less than when concentrated in a small mass. In order to test this point, measurements of the radio-activity of radium bromide were made when in the solid state and when diffused throughout the mass of a solution more than a thousand times the volume occupied by the radium compound.

Two tubes, closed at one end, were taken, in one of which was placed about a milligram of pure solid radium bromide and in the other a solution of radium chloride. The tubes were connected near the top by a cross tube, and the open ends were then sealed by a blowpipe.

Measurements of the radio-activity of the radium were made by means of an electroscope. The tubes, fixed on a stand, were placed in a definite position near an electroscope and the rate of discharge observed. This was due to the β and γ rays emitted by the radium, since the α rays were completely absorbed in the walls of the tube. By placing a lead screen 6 mm. thick between the tubes and the electroscope the rate of discharge was due to the γ rays alone.

After measurements of the activity had been made, the glass apparatus was tilted so as to allow the radium chloride to flow into the arm containing the radium bromide. This dissolved the radium, and part of the emanation was released and distributed itself throughout the tubes.

No appreciable change of the radio-activity of radium was observed over a month's interval. If the rate of production of the emanation, or the excited activity caused by it, had varied during the interval, a corresponding change would have been observed in the rate of discharge due to the γ rays, for other experiments have shown that the amount of γ rays is proportional to the amount of emanation present, provided measurements are made several hours after the introduction of the emanation into a vessel, in order to allow the excited activity to reach a maximum value. The rate of discharge due to the γ rays was somewhat diminished, but this was due to an increased absorption of the β rays by the solution, and not to a change in the rate of emission of these rays. On account of the great penetrating power of the γ rays, the increased absorption due to the presence of the solution was negligible.

Since, after solution, the radium bromide was diffused through a mass of solution at least 1000 times the bulk of the solid radium bromide, we may conclude that a distribution of the radiating matter over a thousand times its original volume has no appreciable influence on its radio-activity.

This experiment shows that, over the range investigated, the radio-activity of radium is not influenced by its own intense radiations. This result is in agreement with previous observations, for neither the radio-activity of any active product nor the rate of loss of its activity has been found to be affected by its degree of concentration.

It is thus improbable that the energy given out by radium is due to an absorption of an unknown external radiation which is similar in character to the radiations which are emitted. Experiments are in progress to test whether still further dilution of the radium solution produces any alteration in its radio-activity. E. Rutherford.

McGill University, Montreal, December 18, 1903.

Relative Motion and Conservation of Energy.

I have received a letter from a correspondent which has led me to think that certain points connected with elementary dynamics are very obscurely put forward in text-books and in elementary class teaching generally. Of these the following may be taken as examples:—

(1) A river is flowing at three miles an hour. If two steamers are ascending the river, making headway at the rate of three miles an hour, one propelled by the action of paddle wheels or a screw, and the other pulling itself up by means of a chain laid along the bed of a river, the former will have to exert twice the horse-power of the latter, although the resistance overcome and the distance travelled in any given time are the same in both cases. Why is this?

(2) If a man is standing in an express train going at sixty miles an hour, he will have to perform exactly the same amount of work to throw a body of mass 1 lb. forwards with a relative velocity of sixty miles an hour as if he threw it backwards with the same relative velocity.

Yet in the former case the kinetic energy of the mass is increased from 121 to 484 foot pounds, while in the latter it is decreased from 121 foot pounds to zero. The actual work done by the man is in every case 121 foot pounds. This result has the appearance of being in contradiction with the principle of work.

I have known many Cambridge lecturers who, when they attempted to solve problems of a similar character, arrived at very different results. I am able to account for the apparent contradictions of the principle of conservation of energy, although I did not learn to do so from text-books. The majority of readers of NATURE are also, doubtless, competent to explain them in their own way and to their own satisfaction. But a student reared on the conventional text-book cannot fail to think (if he exercises his thinking powers at all on the subject) that the laws of dynamics must be at fault somewhere.

G. H. BRYAN.

The Universities and Technical Education.

HAVING just read Prof. Perry's address on "Oxford and Science," I am tempted to give my own views on technical education for the Government service, and especially for the service of India, with which I have been connected since 1869. My qualifications for this discussion are chiefly that I was Director of the Imperial Forest School at Dehra Dun, in India, for five years, and Deputy Director of that school for four years, and during those nine years I always instructed the students personally in one of their branches of study. The excellence of the Dehra Dun Forest School has lately been recognised by the French Government, which has decided to send its Tonquin and Cochin China foresters there to complete their technical training, after having learned European forestry at Nancy.

My experience in India has been that men who have taken university honours degrees in science make the best scientific Government servants, but need special training at a technical college to complete their education for the public service, just as candidates selected for the Indian Medical Service, after receiving a thorough European medical training, complete their education at Netley. The Government of India fully recognises the advantages of a university training for its administrative and judicial service, commonly known as the Indian Civil Service, of which it is the most important branch, also for its Educational and Geological Departments, and the head of the Indian Meteorological Department always comes from a university. Why not also candidates for its Engineering and Forestry Departments? For these important departments, at present, boys are recruited chiefly from the public schools, where they may or may not have acquired the rudiments of scientific knowledge. Surely better candidates could be obtained if the age-limit were raised, and men trained in science and who have obtained an honours degree at a university were taught the technical part of their business at a well equipped Government college, such as the Royal Indian Engineering College, Coopers Hill.

At present there is too much overlapping of studies at technical colleges, and immature students are hurried through their preliminary scientific studies and have not the necessary time to devote to subjects which will form their future life-work. The London medical schools are instances of this. With the best clinical instruction available at the London hospitals, each of these institutions maintains with difficulty a more or less complete staff to teach botany, physiology, &c., which should be taught at a central university. There would be a great saving of expenditure at technical colleges, and much greater efficiency, were the scientific education which is a necessary preliminary to technical knowledge acquired under the distinguished guidance of university professors. By passing through a university, candidates for the higher posts in the Government service would experience the excellent social atmosphere of the university by mixing with men who are preparing for all the different professions and positions in life, and would have a much broader training than is possible at a purely technical college, where there is always the danger of narrow views, and of the overcrowding of subjects of instruction.

I hear that men who have taken a degree at Cambridge in the excellent mechanical school there are readily admitted without paying fees to complete their technical training in large engineering workshops, and surely a wider knowledge of engineering could be obtained at a Government college, such as Coopers Hill, than at any private engineering workshop, where the work done must be of too special a character for Government service. The University of Cambridge does not contemplate being able to turn out finished engineers, but only men preliminarily trained for engineering, neither does it contemplate educating practical foresters, but merely men who have obtained a diploma in the theory of agriculture and forestry. There is a demand in the colonies, as well as in India and Egypt, and by some foreign countries, for English-speaking professors of engineering and forestry, as well as for trained engineers and foresters, and at present the supply of such men is quite inadequate, and frequently these appointments are given to foreigners, simply because properly trained men from our country are not available.

Forestry can be admirably taught at Coopers Hill, with 14,000 acres of the Windsor Forest at our doors, and with examples of forests at Alice Holt Wood, in the Chiltern Hills, and elsewhere, easily accessible by train. The splendid forests of the north of France are within a day's journey, while, after a six months' practical training in the German forests, no forester in the world can be better equipped than are our students. Were our first year students university men instead of schoolboys, America and the colonies would be tempted to send us more students, and one of the finest technical colleges in the world might be easily established.

Coopers Hill, January 1. W. R. FISHER.

Prof. Johannsen on Heredity.

I SHOULD be glad if you would allow me space for some remarks on two recent reviews of Prof. Johannsen's "Erblichkeit in Populationen," in the last issues of *Biometrika* and of NATURE (December 17) respectively, the former signed by Prof. Pearson and Prof. Weldon.

I find it difficult to understand Prof. Johannsen's book in the sense in which the reviewers have, apparently, read it. In both notices it is stated that, if the author's views were correct, the correlation between mother and daughter plants should be perfect. As I take it, however, Prof. Johannsen's view does not imply, and is not consistent with, such a hypothesis; he believes, and adduces evidence to show, that within the pure line "Der Rückschlag ist vollkommen, ganz bis zum Typus der Linie," and explains the result on the hypothesis that the germ-plasm structure (or whatever we may term it) for the pure line is constant, the variations purely somatic. Neither the existence of zero correlation between parent and offspring nor the assumed somatic character of variations, within the pure line, is consistent with perfect correlation between parent and offspring for the race at large. This misunderstanding, in my view, is fundamental.

With reference to the concluding paragraph of the review in NATURE, it may be pointed out that Prof. Johannsen undertook the definite task, clearly stated, of elucidating the nature of intra-racial heredity by the study of heredity within the pure line, *i.e.* the offspring of one self-fertilised individual. He has shown that the intensity of heredity between the first two generations sprung from such a single individual may be vanishingly small, although it is quite sensible within the race at large. The result is of great importance both as regards the theory of heredity and the practice of breeding, and the work cannot be termed in any sense a failure.

One would, certainly, wish that Prof. Johannsen had employed more advanced statistical methods, and one may

(as I do) dissent from some of his conclusions; but the methods he has used are legitimate and sufficient for his immediate purpose, and, in my opinion, the work as a whole is one of the most stimulating contributions to the study of intra-racial heredity published in recent years.

December 22, 1903. G. UDNY YULE.

WITH regard to Mr. Yule's view that there is a fundamental misunderstanding in our notice of Prof. Johannsen's book, we must direct attention to the problem at issue summed up in the words "Der Rückschlag ist vollkommen ganz bis zum Typus der Linie." The character selected for measurement by Prof. Johannsen either fully determines the type or it does not, *i.e.* in the latter case it may be subject to somatic variations having no influence on offspring as Mr. Yule suggests. If it does determine the type, then the correlation between the parent and the mean of the offspring should be perfect, and this it certainly is not. If it does not determine the type, the correlation might be imperfect because the character of the line would not be perfectly known. But since the parental character is in this case not perfectly known, it is clearly impossible for Prof. Johannsen to determine the type, and thus his experiments must fail to show whether the "Rückschlag" is perfect or not. This point is referred to in the reviews cited by Mr. Yule, but it seems to have escaped his notice.

In the next place Mr. Yule *asserts* that Prof. Johannsen has shown that the intensity of heredity between the first two generations sprung from a single individual may be vanishingly small. This is precisely what he has failed to do. To deal with heredity the *same* character must be selected in two successive generations, and this, as pointed out in the review in question, Prof. Johannsen has not attempted.

The remainder of Mr. Yule's letter being neither a reasoned defence of Prof. Johannsen's book nor a criticism of our review calls for little comment; it will command from the reader just that degree of assent which he may be accustomed to give to mere opinion very authoritatively stated. Mr. Yule's estimate of the value of Prof. Johannsen's experiments and statistical methods differs widely from that expressed in our review, but nothing is gained either in criticism or controversy by the mere posing of a rival *ipse dixit*. THE REVIEWER.

The Heat of Radium.

A NUMBER of years ago I published a theory of the formation of the elementary bodies, based on polymerisation and its reversal. The numerics ("atomic weights") of the elements show an increasing accordance with that theory as time goes on.

Of our existing system of numerics the polymerisation points are comprised in the expression n 15; they are, 15, 30, 45, 60, 75, 90, 105, 120, 135, 150, 165, 180, 195, 210, 225, 240. As chemical change in general exhibits a great tendency to run down, we may fairly assume that most of the earlier reversals have already occurred, and that such as remain will be associated with elements of high numeric.

It is clear that polymerisation must involve the emission of heat, and I am strongly disposed to regard radium (Ra = 225) as the product of a "stoff" in the act of polymerisation, the reversal being well indicated by the discharge of helium (He = 4).

It is interesting to notice that Sb (= 119.5) and Sm (= 149.9) are extremely near polymerisation points. It would be worth while to examine compounds of these bodies for emitted heat and gaseous or other matter.

The emanation phenomenon would also appear to be in some way related to the same points. It is, for example, stronger in U (= 238) than in Th (= 231.7). Both these bodies, and the substances they emit, should be derived from a hitherto unknown polymer (= 240) undergoing reversal into simpler bodies. EDMUND J. MILLS.

January 4.

Rocket Lightning.

MY attention has been directed to a letter in your issue of October 22, 1903, describing certain flashes of lightning that were visible on July 22. In many respects the flashes corresponded with flashes seen by myself and friends at the same hour on the same evening, but the discrepancies are remarkable. For instance, Mr. Everett, in the letter referred to, saw flashes "bearing a strong resemblance to ascending rockets, a luminous trail shot up about as fast as, or rather faster than, a rocket," whereas we saw flashes that appeared with about the ordinary rapidity. There certainly was a strong suggestion of ascension, but vertical lightning flashes quite commonly exhibit this appearance, which sometimes at least is due to an optical illusion.

The bearing of the flashes as seen by us, from the verandah of a house in Camac Street, was N. 143° W., and as the Sibpur College bears, from our position, N. 86° W., about 16,500 feet distant, it would be quite easy to calculate the position of the flashes if Mr. Everett had noted their bearing accurately. His description of the bearing as "in the S.S.W." suggests that this is only intended as a general indication of the direction. If S.S.W. were the exact direction, the flashes could only have been 10½ miles distant from Mr. Everett and 12 miles from us, but if the direction were the next point of the compass, S.W. by S., the flashes were 50 miles away. This greater distance is probably nearer the truth, because if the flashes were only 10 or 15 miles distant thunder would have been audible.

Again, the angular altitude of the highest part of the flash is given by Mr. Everett as "15° or so," which does not agree with our observation of 10° or a trifle under, perhaps nearer to 9°. At a distance of even 30 miles there should have been no observed difference of maximum altitude between Mr. Everett's observation and ours.

In other respects the observations tally precisely. The vertical flashes appeared repeatedly in the same position against a background of clear sky, so clear that a star, ζ Centauri, was visible at an altitude exceeded by the flash.

Mr. Everett falls into an error in supposing that the lightning "must have occurred at a spot above the Sunderbunds." The direction of the Sunderbunds is not westerly, but easterly from the Sibpur College, and the flashes must have been over some part of the Twenty-four Perganas if not more than 25 miles away, over the Midnapore district if more than 35.

As to there being "not a score of men in all Bengal who would take a serious interest in such lightning if they did happen to see it," I am not aware of the precise number, and can only vouch for three, the manager of a railway, another competent observer, and myself, who observed together, but I should not be surprised if the flashes were also seen by other observers equally able to record their observations accurately. W. A. LEE.

Calcutta, December 10, 1903.

I GATHER from Mr. Lee's account that he only witnessed one kind of lightning, whereas my son's letter describes two kinds altogether different in appearance. The inference would seem to be that the less brilliant and more unusual kind was not visible in the centre of Calcutta, though visible at Sibpur, probably owing to better atmospheric conditions. J. D. EVERETT.

11 Leopold Road, Ealing, December 30, 1903.

The Recent Leonid Shower.

THE results of the observations by M. Eginitis of the recent Leonid shower indicate that there was another maximum on the night of November 15, occurring several hours previously to that seen by observers situated in or near the longitude of Greenwich. This early maximum was evidently of a very distinct character at Athens, as the observations showed a regular increase and decrease of meteoric frequency before and after the time of culmination (15–16h., local time), the watch having been prolonged for some hours further, or until 17h. 50m. Athens was evidently too far east to permit observers there taking cognisance of the later outburst of meteoric activity that added considerably to the strength of the shower here. The maximum mentioned by M. Eginitis does not appear to have been very noticeable as such to British observers, though it was anticipated here that that event should occur on November 15 at 13h. 30m. G.M.T., the calculated maximum thus falling within the hour, when we allow for the difference of longitude, during which it was actually observed at Athens. The later maximum came altogether unexpected. It is noteworthy that these maxima seem to have been characterised by quite a distinct type of meteor.

Dublin. JOHN R. HENRY.

CENTRAL ASIAN EXPLORATION.[1]

DR. SVEN HEDIN'S latest book possesses an interest for the great world of travellers which is apart from its intrinsic merit as a traveller's record. The blank spaces of the world's map are becoming so narrow; there is so little left for the exploring enthusiast to mark with his pioneer footsteps, that books of this nature must necessarily grow scarcer as the world grows older. This may be one of the last of a grand series which has educated the world (in divers tongues) since the days of Herodotus. The finger of the North Pole still beckons to us, as does that of the South; there are still a few sand wastes in the interior of Arabia, and a few thousands of forest leagues in the interior of South America which have not yielded up their secrets to the keen eye of scientific inquiry—but that is about all. It is the unattractive emptiness of the wildest and most desolate wastes which still remains to be explored, so that the tale which has yet to be told of them will be told by none but men of the true race of the world's heroes of research men of the stamp of Peary and Sven Hedin—who explore because, to them, the first acquisition of knowledge of the unknown is the one thing that makes life worth living.

The story that is now told by Sven Hedin is one of stirring personal adventure leading to discoveries in a very old world rather than in a new one, and instinct with the interest of human history. He tells it well, introducing to us the companions of his travels one by one, making us acquainted with their weaknesses and their strength, familiarising us with his surroundings, his horses, and his dogs (and even those usually uninteresting brutes, his camels), until we can see the whole of this little Central Asian caravan moving across the deserts and through the mountain defiles as if we were one with them, hoping their hopes, fearing their fears, and deploring with them the loss of those brave helpers who fall by the way. No novel could carry the reader along with the course of its plots and its evolutions until the final dénouement more completely. Sven Hedin is a good English scholar himself, and he is to be congratulated on his choice of a translator. Very few books of travel written, as this is, in diary form avoid the Scylla of dulness without wreck on the Charybdis of untruth. A little poetic licence is usually necessary to enliven the narrative. But here any man who has seen anything of those remote Asiatic fields which Sven Hedin describes, recognises at once the atmosphere of absolute truthfulness in which the drama moves. There is not a risk incurred, not a danger (and the whole record is full of them) escaped, which is not the natural sequel of the daring conception of each phase of the three years' journeying—not one which any traveller could reasonably have hoped to avoid had he marked out for himself Sven Hedin's expeditions with Sven Hedin's courage.

His first enterprise, the voyage down the Tarim River, to its ending in the desert, illustrates the marvellous patience and pertinacity of the man. To most people it would have been enough to glide gently down the stream watching the changing lights and shadows and the glorious autumn tinting of the poplar woods, and to have made a record at the end of each day's run of its general direction and its terminal latitude. This was not good enough for Sven Hedin. Hour after hour he sat at his work in the boat, mapping each turn, each curve, in the twisting, winding stream, noting its depth, the strength of its current and its peculiarities, until sometimes sixteen hours a day of intermittent work was achieved without once leaving his table. If genius is an "infinite capacity for taking pains," then indeed does Sven Hedin possess that desirable attribute. It must be noted, too, that in a desert like that of the Takla Makan, such natural hydrographic features as exist must inevitably change almost from year to year. There is no more permanency about the course of the Tarim River than there is about the "locus" of Lop Nor. All Sven Hedin's magnificent map making may require serious correction within the next few years.

The very centre of interest in Central Asian geography lies in the Lop Nor region. The former existence of a high road across the desert connecting the outlying city of Western China, Sachow (Saitu), with Yarkand and Kashgar by a route skirting the northern spurs and outlying ridges of the Altyn Tagh (Astyn Tagh, according to Sven Hedin) to Cherchen, and

FIG. 1.—Tibetan Soldiers. (From "Central Asia and Tibet.")

thence following the Cherchen River until it again touches the northern foot hills of the Kuen Lun, and thus extends itself to Nia and Khotan, has long been recognised; but we must now accept the theory of a more direct road westward connecting Sachow with the ancient city of Lou Lan, so well described in Sven Hedin's book. Lou Lan was a small and independent State in the early centuries of our era, dovetailed as a buffer between China and the Turkish Hun tribes, who together appear to have rendered its political life as uneasy as more modern buffer States have found such a life to be. That this isolated State existed only by grace of the existence of the Lop Nor Lake is sufficiently proved by its total disappearance when the waters of Lop Nor (the old bed of which lake is placed further north by Sven Hedin than our existing maps show it—about midway between the Altyn Tagh on the south, and the Kurruk Tagh on the north) shifted southward. This was no case of sand burying. The whole water supply of the district gradually withdrew to another position, forming new lakes on the inconceivably flat surface of the desert some fifty miles away; and the extraordinary feature about this move-

[1] "Central Asia and Tibet." By Sven Hedin. Vol. i., pp. xvii+608; vol. ii., pp. xiv+664. (London: Hurst and Blackett, Ltd., 1903.) Price 42s. net.

ment is that the lakes which were so formed appear now, after many centuries, to be in the process of transferring themselves once again to their old place, the place which was assigned to them in early Chinese maps.

It is characteristic of the thoroughness of the work of this great traveller that he actually levelled the land surface between the ancient Lop Nor depression and the Kara Koshun (the present lake bed), and has proved beyond dispute the theory of a migratory, or moving, lake. That Lou Lan was Buddhist is sufficiently attested, not only by the nature of the relics discovered on its site, but by the peculiar construction of those solid brick erections which Sven Hedin calls towers, but of which the photographs quite clearly indicate the nature. They are Buddhist topes or stupas. Thus we have another link in the long chain of Buddhist centres (temples and holy places) stretching from Western China through the deserts, past the group of towns unearthed by Stein, broken for a soace by the intervening Himalayas, and then recommencing in the valleys of Gilgit, Darel and Swat, until it ended in the valley of Peshawar.

The last part of Sven Hedin's story is devoted to

FIG. 2.—Ruined house with its doorway standing *in situ*. (From "Central Asia and Tibet.")

his gallant but unsuccessful attempt to reach Lhasa. Beyond doubt he was betrayed by the Mongol pilgrims whom he encountered early in his journey. The Lhasa authorities were fully informed, and the attempt was foredoomed to failure. None the less was it a most instructive journey. It hardly needed the evidence of the distinguished traveller to prove that Tibetans possess civilised and humane instincts. They do not necessarily ill-use a casual visitor to their country who can make himself intelligible and agreeable, but they will not admit the European within the gates of their holy city—if they can help it. We now have more material with which to construct the maps of that dreary, storm-swept, inhospitable waste which lies between the Altyn Tagh and the oasis of the Sanpo (Brahmaputra). The identification of the ancient bed of the Lop Nor and the site of Lou Lan; the elimination from our maps of the Gobi Mountains and the eastern extension of the Kurruk Range; the detailed survey of the Tarim River and the determination of the levels of the desert surface south of Lop Nor, together with the results of a vast area of geographical research on the north coast of Tibet, are records of which even Sven Hedin may be proud. To the world at large he is already known as a great geographer and an intrepid explorer. Hereafter he will be recognised as a most fascinating writer even by those who care little for geography.

T. H. H.

WATER SUPPLY AND IRRIGATION IN THE UNITED STATES.

FOR the last fourteen years very great attention has been paid by the Geological Department of the Government of the United States to the water resources of the country, and in acquiring trustworthy information as to the same.

There has recently been issued from the Government Press at Washington fifteen volumes of reports, and water supply and irrigation papers, bearing on the yield of the rivers, the various methods adopted for gauging the flow and obtaining sectional measurements, artesian wells and the flow and yield of underground water, the means adopted for storage, the use of water for the supply of towns for irrigation and for power purposes, and the pollution of rivers from sewage and other causes.[1]

The greater part of these reports is taken up with records of the observations of the staff engaged in measuring the rivers in the different States and obtaining information as to water supply, which, although mainly of use to engineers in the United States, might also be interesting and instructive to those engaged in the water supply of this country.

The report No. 76 by Mr. Pressey on the flow of rivers in the vicinity of New York State is of special interest, as it deals in a comprehensive manner with the methods adopted for obtaining trustworthy information as to the yield of rivers, and gives details as to the methods adopted for obtaining the measurements necessary for the purpose.

The author of this report considers that one of the chief resources of the United States consists in its water. The prominent industrial position of several States is due largely to the abundance of available water, and the rivers with their great water power have been in the past, and will continue to be in the future, a perpetual source of wealth. Contrary to what might have been expected, Mr. Pressey is of opinion that there never was a period in the history of the United States when the development of water power has made such strides as recently, the increase in the utilisation of water power for the period 1890–1900 being 30 per cent., or 472,361 horse power. In the State of Maine the developed power increased 60 per cent.

The rivers as water suppliers are also of inestimable value in the arid regions of the coastal States, where without an artificial supply of water there cannot be any vegetation, and where large areas have been reclaimed and made into agricultural land of great fertility by storing and distributing the water over their soils. This subject was shortly dealt with in the notice in NATURE of April 30, 1903, on the irrigation in the Western States of America, and of the report of the Mexico College of Agriculture in NATURE of August 27, 1903.

The Geological Department has for the last fourteen

[1] Copies of these reports may be obtained through Messrs. King and Son, Great Smith Street, Westminster.

years been engaged in ascertaining the value of the rivers as water suppliers and in furnishing information upon which to base estimates of the available supply. The want of this information has frequently led to the most disastrous mistakes in the construction of hydraulic works. From ignorance of the hydrographic condition of the drainage basin of the stream, and of the region in which the stream is located, engineers have in many cases been misled by the only information available, that of the "oldest inhabitant," which may be trustworthy as to the highest level to which the water has reached in floods, but is frequently very misleading as to the low water conditions of the river. Amongst other instances recorded is one where, after an expenditure of 32,000*l.* in hydraulic works by a town where it was expected the water from a neighbouring river would be capable of developing 14,000 horse power and cause it to become a manufacturing centre, it was found that the estimate had been based upon a miscalculation as to what the river could yield to the extent of 500 per cent.

Even where statistics as to the rainfall are available, these may be very misleading so far as the yield of the drainage area is concerned unless checked by stream measurements. An instance is quoted where a calculation of the minimum yield of a river in one of the States was made independently by five experienced engineers, the quantity varying from 0·20 to 0·40 cubic foot per second per square mile.

The various forms of floats used to determine the velocity of streams are discussed in the report. For reconnaissance works surface floats have been found most convenient and approximately trustworthy. Rod floats consisting of cylindrical tubes or wooden rods 2 to 3 inches in diameter, weighted at the bottom, are considered as more trustworthy than double floats having the subsurface float connected to the upper one by a silk cord.

The current meter, on the whole, has been found to be best adapted to the general measurements made in the United States Survey. One method of using this

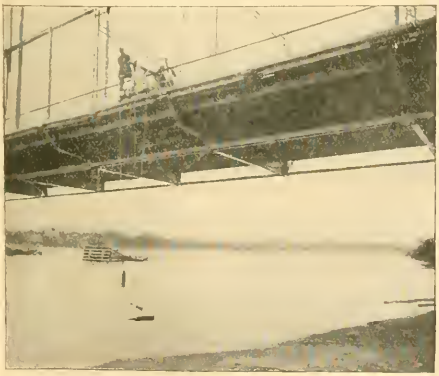

FIG. 1.—Current Meter in Use, Suspended from a Bridge.

in a wide channel is shown in the illustration (Fig. 1). In the second illustration (Fig. 2) the measurements are shown as being taken from a cable having 200 feet span placed across the stream, and supported on the right bank by timber shears 25 feet high, and on the left side anchored to a large buried oak.

As the result of a great number of observations it has been found by the United States surveyors that the mean velocity of a stream is generally found to be at six-tenths of the depth of the water measured from the surface for wide shallow rivers, which figure should be increased to two-thirds in the case of canals and flumes or narrow natural channels. The velocity generally increases from the surface downward to

FIG. 2.—Cable and Car used to Measure Discharge of River.

about one-tenth of the depth, and then decreases to the bottom, where it reaches the minimum.

Where more than one observation was made upon the channel, the ratio between the surface and mean velocities in a stream was found, on the average of a number of experiments in different rivers, to be 0·88 of the mean of the surface velocities taken in the vertical in which the floats were run. Where only one surface float was used in the centre of the river, the coefficient was on an average found to be 0·80. The chances of error are greater where only one float is used. For shallow depths of from 3 to 8 feet the coefficient for the mean velocity varied from 0·92 to 0·82. For large deep rivers, such as the Mississippi, Humphrey's and Abbot's observations gave a coefficient of 0·98.

Measurements are also recorded of the flow of water under ice. The observations were made by cutting holes large enough to admit a current meter. In an ice-covered channel a decided drag occurs at the surface as well as at the bottom. Two points of mean velocity were found to exist in the vertical at about 0·13 and 0·73 of the depth, the maximum being at 0·35 of the depth. The best result was obtained by holding the current meter at two-thirds of the depth and applying a coefficient of 0·95 to the observed velocity at that point.

For providing uniformity in the reports of the various observers as to the quality of the water, the following standard of turbidity was used for field observations. The figure 100 was taken to represent a water containing 100 parts of silica per million, in such a state of fineness that a bright platinum wire one millimetre in diameter can just be visible when the centre of the wire is 100 millimetres below the surface of the water, the eye of the observer being 1·20 metres above the wire, the observation being made in the middle of the day, in the open air, but not in sunlight.

For taking observations a graduated rod with a platinum wire projecting from it at right angles was

used (Fig. 3), on which the graduation mark of 100 is placed on the head at a distance of 100 millimetres from the centre of the wire. When this rod is immersed in water the visibility of the projecting wire at the depth from the surface determines the degree of turbidity according to a scale given in the report. This varies from a turbidity of 7 degrees at a depth of 1095 millimetres to 100 degrees at 100 millimetres depth, 1000 degrees at 21 millimetres, and 3000 degrees at 12 millimetres. When platinum wire is not easily obtainable a clean bright pin will serve the purpose, and where observations cannot readily be made in the stream, a pail or tub filled with the water may be used, the diameter of which should be twice the depth at which the wire is immersed. Where the turbidity is more than 500, that is, where the wire cannot be seen through an inch of water, the water to be gauged should be diluted with clean water, the turbidity being multiplied by the ratio that the total volume of water bears to the water in the mixture.

In report No. 67, on the motion of underground water, by Mr. S. Slichter, it is stated that the lowest theoretical limit at which ground waters can exist is reached when the pressure in the rocks, due to the weight of the superincumbent material, is so enormous

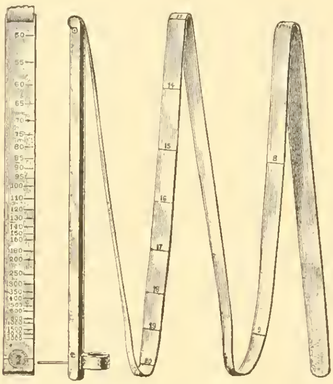

FIG. 3.—Folding Turbidity Stick.

that all cavities and pores are completely closed. This limit, it is calculated, is reached at 6 miles. The land surface of the globe covers 52,000,000, and the water surface 144,700,000 square miles. Taking the average pore space of the surface rocks occupied by water or moisture at 10 per cent., the amount of ground water is estimated at 565,000 million million cubic yards.

On this basis the underground water would be sufficient to cover the entire surface of the earth to a uniform depth of from 3000 to 3500 feet. The ground water is estimated to be about one-third the amount of the oceanic water.

The rate of movement of water through soil and rocks depends on the size of the pores of the water-bearing medium and the pressure gradient or head due to gravity. All rocks are more or less pervious to water. The porosity of quartz sand varies from 30 to 40 per cent. of the bulk. Sandstone rocks fit for building purposes contain from 5 to 25 per cent. of porosity, limestone from 1 to 13 per cent., while granite has about one-half per cent.

The water contained in porous soils and rocks possesses a slow but definite motion, and moves in an underground current for the same reason that water moves in surface streams, flowing from a higher to a lower level.

The flow varies as the square of the size of the grains of soil, and so if the size of the soil grain be doubled, the flow of water is quadrupled.

American experience agrees with the result arrived at by French engineers that the average velocity through sands is about a mile a year.

The general trend of moving underground water under the influence of gravity is into the neighbouring streams and lakes, but the geological conditions may be such as to force the water above the surface of the ground and form springs, or it may take a general course down the thalweg and towards the sea within the porous medium itself, and so constitute an underground stream at great depth and several miles in breadth.

THE WORK OF THE REICHSANSTALT.[1]

THE third volume of the *Transactions* of the Reichsanstalt was noticed in these pages some two and a half years ago. The part under review at present gives an account of the larger researches which have gone on since that date, and affords ample proof of the fact that the staff of the institution has no intention of departing from the high standard of accuracy and excellence we have learnt to expect in their work.

As in the previous volume, the first paper deals with the work of the director of the second division, Dr. Thiessen, who has continued his researches into the dilatation of solids and liquids, and has determined the dilatation of water from 50° C. to 100° C., thus completing his study from its freezing point to its boiling point.

The range from 0° C. to 40° C. had been covered by Chappuis, and the small differences between his results and those of Thiessen were noted in our former article (NATURE, April 25, 1901).

The method of balancing columns employed in the earlier research was used again, the water in the column at high temperature being in each case jacketed by a tube containing the vapour of some liquid boiling at that temperature. Dr. Thiessen shows that above 25° the following formula represents the results with considerable accuracy:—

$$\rho = 1 - \frac{(t - 3{\cdot}98)^2}{568290} \cdot \frac{t + 343}{t + 72{\cdot}75},$$

while, to continue the table given in our previous article, the actual densities found were the following:—

Temperature	Density
56°	0·985243
65°	0·980594
78°	0·973068
100°	0·958380

Another paper which brings earlier work up to date is that by Jaeger and Dieselhorst on the mercury standard of resistance. In consequence mainly of difficulties arising from electric traction, the method of comparing the resistances of the tubes by the use of the differential galvanometer has been abandoned, the Kelvin double bridge being used in its stead.

Calling M the mean of the resistances of four manganin coils of about one ohm resistance, we have the following series of values:

Nov. 1893	M = 1·001737	ohms at 18° C.
June 1895	M = 37	,, ,,
June 1897	M = 44	,, ,,
March 1903	M = 48	,, ,,

[1] "Wissenschaftliche Abhandlungen der Physikalisch-Technischen Reichsanstalt," vol. iv. part i.

The greatest difference between the value of M determined by observation on any one tube and the mean is 15·5 parts in one million, while the greatest change that has taken place in the value of any one of the manganin standards of the first division relative to the tubes is 45 parts in one million.

Dr. Scheel has an interesting paper on the expansion of solids, describing a series of experiments using the Pulfrich form of the Fizeau dilatometer. The method leads to results of great accuracy for expansions at temperatures up to that of the boiling point of water; it is interesting to note that for Berlin porcelain, the expansion of which is of importance in connection with its use in the air thermometer, the author confirms the result of Chappuis and Harker. Holborn and Gruneisen had found that at high temperatures, say 600° C., the expansion is much less than would be inferred from a formula extending over a range from 0° C. to 100° C. In this respect the porcelain resembles fused quartz.

In another paper Lummer and Gehrcke discuss in a very complete manner the optical properties of dispersion apparatus of high resolving power, while reference must be made to two papers, on the scattering of particles from heated metallic surfaces, especially those of the platinum group, and on the scattering of particles from kathode surfaces in a vacuum.

It is clear from this brief notice that the range covered is a wide one, and that the Reichsanstalt is still continuing to advance our knowledge in a notable degree.

RECENT GEOLOGICAL OBSERVATIONS IN CAPE COLONY.[1]

WHEN Dr. Edward Brown, in 1669, carried the fame of the Royal Society across Europe, and quietly pursued his antiquarian inquiries, he remarked that there were "Wars at that time when I was in this Country, between the Elector Palatine and the Duke of Lorrain." In a similar spirit, the geologists of the Cape Commission have continued their conscientious work in a land divided and subdivided against itself, merely transferring their activity to the Transkeian Territories, when geological observation became incompatible "with the necessities of Martial Law" (1901 report, p. 4). The course of a struggle which at one time threatened the Empire is referred to as "the military problem"; the serene permanence of scientific work has seldom been more aptly illustrated.

The region to which the assistant geologists were temporarily exiled lay on the south-east coast of Cape Colony, between the Great Kei River and the frontier of Natal, in native territories where military rule was not proclaimed. In the spring of 1901, however, observations had been rendered possible nearer headquarters, in the divisions of Swellendam and Riversdale. These led to some corrections of the map issued in 1897. Messrs. Rogers and Schwarz point out how the possibly Cretaceous Uitenhage series can often be distinguished from the overlying gravels only by the occurrence of fragments of a quartzite in the latter. This quartzite is a well marked rock that caps the Uitenhage series unconformably.

The same authors, who then formed the field-staff of the survey, describe the general features of the lands examined beyond the Skei. Unlike the western portion of the Colony, there are here no folded mountains near the coast, and the moisture-laden air from the sea penetrates in consequence far inland. The rivers come down from the Storm Bergen and Drakensberg ranges, and cut steep valleys through the vast steps formed by successively elevated "coastal plains." From the coast inwards, we may move along the edge of the same stratum, on the line of strike of a great synclinal. Starting from its axis, about the mouth of the Kei River, older and older beds are met with as we go north-east. In Kentani, the first division, the igneous intrusive masses are so abundant as to obscure the stratified deposits of Karroo age, and seem (p. 31) to have eaten up the latter in making a place for themselves in the crust. The variations from dolerite to granite appear to have originated in a single magma. On nearing Pondoland, the Dwyka Conglomerate, of Lower Karroo age, and always important as a lithological horizon, occurs with its characteristic glaciated boulders. The Table Mountain Sandstone of the Cape system comes out uncrumpled from beneath it. The most interesting work done in Pondoland was the more detailed examination of the Cretaceous beds, already brought to notice by Baily and Garden in 1855, and by Griesbach in 1871. The lower layers contain rolled chelonian bones, and were deposited in shallow water. Among the "superficial," or post-Cretaceous, beds of Kentani is (p. 66) a fossiliferous quartzite of fresh-water origin.

The report for 1902 sees Mr. Rogers installed as acting or chief geologist in place of Dr. Corstorphine, who has been tempted northwards. Mr. A. L. du Toit, himself a colonial, as we are happy to observe, joins the staff as an assistant. The main work for 1902 lay in Matatiele, up against the Drakensberg Range, and still in native territories. The intimate connection of volcanic energy with the range is shown by the discovery of a chain of nineteen vents, in addition to five recorded to the south-west by Mr. Dunn as far back as 1878. They are filled with dolerite or agglomerate, the latter consisting largely of blown-up sedimentary material. The lavas that flowed from them, in Jurassic times, over the upper beds of the Karroo system, have been weathered away on the south-east, but are preserved upon the north-west slope. Mr. Schwarz points out (report for 1902, pp. 51 and 60) how the trend of the volcanic line is related to persistent north-east and south-west axes of folding, which have determined in the past the coast-line of this part of Africa. The old eastern continent had receded, by Jurassic times, as far as the line of volcanic vents; a later uplift must have been followed by subsidence, whereby the present Transkeian coast-line was determined. The edge of the Drakensberg plateau may thus be regarded as the crest of a uniclinal fold, the native territories lying on the lower limb.

The strata encountered range down from the "Cave Sandstone," which may be partly of explosive origin, to permo-Carboniferous beds. All these are included in the convenient but too comprehensive Karroo system (p. 103), though the upper zones may be as modern as the Jurassic period. Indications of reptilian remains are already known (p. 32). The "Molteno beds," more recent than the famous Theriodont horizons of the Karroo system, contain thin coals and oil shales. The natives at present use ox-droppings for fuel, and thus deprive the poor soil of a valuable fertilising agent.

Work was also done in the typical Karroo district, south of the Nieuweveld escarpment, where new discoveries of Pareiasaurus have resulted. Considerable pains have been taken to place the collections of the Commission in the hands of specialists for determin-

[1] Cape of Good Hope. Department of Agriculture. Annual Reports of the Geological Commission for 1901 and 1902. (Cape Town: *Cape Times* Ltd., Government Printers, 1902 and 1903 respectively.)

ation, and no one who has seen the development of the reptilian material from its matrix under the care of Prof. H. G. Seeley can regret that certain specimens, at any rate, have travelled across the sea to England. G. A. J. C.

THE CLIMATE OF SOUTH AMERICA.[1]

IN the volume mentioned below, all the mean values of the meteorological elements which constitute the climate of the country in question are brought together, these values being deduced from a long series of observations terminating with the year 1900. When it is mentioned that the country embraces 33° of latitude, the surface of which slopes from the shores of the Atlantic on the east to the snow-clad summits of the central range of the Andes on the west, the reader must not be surprised if he finds great differences in the atmospheric conditions that prevail in the various parts of the Republic.

A thorough knowledge of the changes in the meteorological elements in this the South American portion of the globe will prove of great importance to us dwellers in the Old World, for although we are separated so widely as regards distance, we are intimately connected meteorologically. It is quite within the bounds of possibility that our great dependency India and the region about it (and indirectly the British Isles and Europe generally) may be able to check their long period forecasts on observations made in the Argentine Republic.

In this volume an English translation accompanies the Spanish text, so that the book is available to those who cannot read the latter language. In addition to the numerous tables showing the mean daily and annual variations of the elements, accompanied by an excellent statement in each case, Prof. Davis has given a set of twenty-six plates which illustrate graphically not only these variations, but the mean conditions which prevail over this extensive area.

For many of the elements the monthly and yearly values for each year since the commencement of observation are included, but an omission is made in the case of atmospheric pressure. Recent investigations have indicated that the variations from year to year over the South American continent, more especially about the region of Cordoba, are the inverse of those about the region surrounding the Indian Ocean, that is, when the mean pressure for the year is high in Cordoba it is low in India; the insertion of the pressure values in this volume for one station, namely, Cordoba, would have been very useful.

For climatological reasons it is necessary to study the readings of many barometers well scattered over a country, hence the statement on p. 45 that "observations of atmospheric pressure, however complete, are of little practical value if confined to a single place. . . ." It is important, however, to bear in mind that complete series of barometric observations at two stations, one set to check the other, are quite sufficient in many parts of the world to study the changes over large areas from year to year.

The publication of this volume will undoubtedly be welcomed by meteorologists and those who wish to make themselves acquainted with the weather of the region surveyed, and the very complete manner in which the information has been brought together in this convenient form should add to its usefulness.

W. J. S. L.

[1] "Climate of the Argentine Republic." Compiled from Observations made to the end of the Year 1900. By Walter G. Davis, Director of the Argentine Meteorological Office. Pp 154; 26 plates. (Published by the Ministry of Agriculture.)

NOTES.

A CIRCULAR signed by Prof. A. Tonelli and Prof. V. Cerruti announces that it is proposed to erect a memorial in honour of the late Prof. Luigi Cremona, professor of higher geometry in the University of Rome, and director of the engineering school. The fame of Prof. Cremona is world-wide, and his works have exercised a great influence on research in fields of pure and applied mathematics. It is intended that the monument to his memory shall be an international one; and the hope is expressed that all who have been inspired by his discoveries, or have regard for his genius, will contribute to the fund being raised. Subscriptions should be sent to Signor I. Sonzogno, Piazza San Pietro in Vincoli, 5, Rome.

AT a meeting of the Bath Town Council on Tuesday, mention was made of the fact that helium has been found in gases from the largest and perhaps the best known of the city's hot mineral springs, the King's Bath. The deposits that collect in the tanks and pipes at the three springs have also been investigated. A few weeks ago a quantity of the deposit from the new Royal spring was obtained and sent to the Hon. R. J. Strutt, who, in a communication to the Baths Committee, remarks:—"My experiments have led to some conclusions which may, I hope, interest the committee. I have found that the deposit contains radium in appreciable quantities, though I am sorry to say not enough to pay for extraction. It will be remembered that the gas which bubbles up from the springs contains a small proportion of helium. Sir William Ramsay has recently made the most important discovery that radium slowly evolves helium by a spontaneous change. I think there can be little doubt that the helium of Bath owes its origin to large quantities of radium at a great depth below the earth's surface. A little of this radium is carried up by the rush of hot water and is found in the deposit. My experiments promise further interesting developments, which I shall have much pleasure in bringing to the notice of the committee in due course."

A MEETING was held in the house of the Zoological Society on Tuesday to consider proposals for the organisation of zoologists. Forty-one zoologists from England, Scotland and Ireland attended the meeting. The following resolution was carried by a large majority:—"That it is desirable that the zoologists of Great Britain and Ireland be organised for the consideration of all matters affecting the interests of zoology and zoologists, and to take such action as may seem desirable." A committee consisting of Prof. Cossar Ewart, Prof. Bridge, Prof. Hickson, Dr. Scharff, Dr. G. C. Bourne, Dr. Ridewood, and Mr. Cunningham was appointed to draw up a scheme.

WE are glad to see among the New Year honours gazetted by the India Office the name of Dr. W. T. Blanford, F.R.S., who has been made a Companion of the Order of the Indian Empire. Dr. Blanford, whose services to Indian geology and zoology are known to all our readers, joined the Geological Survey shortly before the outbreak of the mutiny, and is one of the few civilians entitled to wear a Mutiny medal.

ON New Year's Day we had the pleasure of inspecting a series of the well-known animal photographs of the Messrs. Kearton now being exhibited to the public at 175 Bond Street. All these reproductions from the original photographs have been considerably enlarged, although not to such an extent as to impair the sharpness or blur the

details. The owners are to be congratulated, not only on the general character of the exhibition, but likewise on the fact that none of the photos have been "touched up." Mr. Cherry Kearton specially prides himself on the photo of a great crested grebe on her nest, which took seven days' watching before it could be secured.

SIR WILLIAM RAMSAY, K.C.B., will, we learn from *Science*, give a course of lectures during the summer session at the University of California on "The Constituents of the Atmosphere and the Emanations from Radium."

THE year 1905 being the tenth anniversary of Röntgen's discovery of the X-rays, it is proposed to commemorate the occasion by holding in Berlin a Röntgen congress, together with a Röntgen exhibition. Information regarding the arrangements will be obtainable from Prof. R. Eberlein or Dr. Immelmann, of Berlin.

A SPECIAL meeting of the Berlin Geographical Society will be held on January 13 to greet the members of the German Antarctic Expedition and receive the report of Prof. E. von Drygalski on the course and results of the expedition. An address will be given by Prof. Vanhöffen on the fauna of south polar regions.

ON Tuesday next, January 12, Prof. L. C. Miall will commence a course of six lectures at the Royal Institution on the "Development and Transformations of Animals." On Thursday, January 14, Mr. G. R. M. Murray will deliver the first of three lectures on the "Flora of the Ocean," and on Saturday, January 16, Mr. J. A. Fuller-Maitland will begin a course of three lectures on "British Folk-Song." The Friday evening discourse on January 15 will be delivered by the Right Hon. Lord Rayleigh, his subject being "Shadows"; on January 22 by the Rev. W. Sidgreaves, on "Spectroscopic Studies of Astrophysical Problems at Stonyhurst College Observatory"; and on January 29 by Mr. D. G. Hogarth, on "The Marshes of the Nile Delta."

CAPTAINS S. P. JAMES AND W. GLEN LISTON, of the Indian Medical Service, write from Simla to point out that the third volume of Mr. F. V. Theobald's work on the Culicidæ contains reproductions of portions of plates which they have prepared for a monograph on Indian Anopheles, and that statements are made in a number of cases without reference to the work of the individual observers upon whose results they are based. We have referred the matter to Mr. Theobald, who writes:—"I much regret that the plates and information to which they refer should have been published without acknowledgment in my book. The omission was due entirely to inadvertence, occasioned by the press of matter calling for record in the work. Steps are being taken to remedy the error."

WE learn from *Science* that the following Bill has been introduced into the U.S. House of Representatives and referred to the committee on coinage, weights and measures:—"*Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled*, That on and after the first day of January, nineteen hundred and five, all the Departments of the Government of the United States, in the transaction of all business requiring the use of weight and measurement, except in completing the survey of public lands, shall employ and use only the weights and measures of the metric system; and on and after the first day of January, nineteen hundred and six, the weights and measures of the metric system shall be the legal standard weights and measures of and in the United States."

THE Australian mail has brought the report of the meeting of the Linnean Society of New South Wales on November 25 last, from which we learn that the chairman made a preliminary announcement respecting the Macleay fellowships endowment—the late Sir William Macleay's last and crowning benefaction to science. Subject to a life-interest in the principal on the part of his widow, lately deceased, Sir William bequeathed to the Society the sum of 35,000*l*. for the foundation and endowment of research fellowships, tenable by graduates in science of the University of Sydney upon certain conditions specified in the testamentary directions. On October 24, 1903, the executors paid to the Society the sum of 33,250*l*., which the council has since invested at 4 per cent. per annum. The council does not expect to be in a position to make appointments to the fellowships before about the middle of this year.

THE *Times* publishes the following communication from its Madrid correspondent:—"In anticipation of the total eclipse of the sun of August, 1905, the papers are beginning to urge the Government to include in the Estimates for 1904 an item providing for a scientific mission of Spanish astronomers to be sent abroad, in order to study in foreign observatories the latest methods of investigating the phenomenon. For the eclipse of 1900 the Cortes voted 190,000 pesetas, but the measure was taken so late that the money was spent at a loss. It may be mentioned that the zone of about 200 kilometres covered by the eclipse of 1905 traverses Spain from Galicia and Asturias to Valencia and Castellon. The northern coast between Coruña and San Vicente de la Barquera, and the eastern from Valencia to the Gulf of San Jorge will be included in the zone of total obscurity. Observers at Ferrol, Lugo, Oviédo, Gijon, Léon, Palencia, Burgos, Soria, Teruel, and Saragossa will have some four minutes in which to make their observations. Madrid lies to the south of the zone of total eclipse. It would be well if foreign astronomers would lend their sympathy to Spanish students to facilitate the preparations for the most effective utilisation of these precious moments."

WITH the daily weather report for January 1 the Meteorological Office issued a small subsidiary chart showing the total rainfall in 1903 at those stations which report by telegraph, together with the percentages of the average annual fall for the thirty-five years 1866–1900. The chart shows very clearly the general distribution of the rainfall of the year, so far as it is represented by the stations referred to. The greatest fall, 67 inches, occurred at Valencia, 120 per cent. of the yearly average. At Stornoway the amount was 62 inches, 133 per cent. of the average (46·62 inches), this latter value being nearly 10 inches less than the normal fall at Valencia. The smallest falls occurred on the east and south-east coasts of England; at Yarmouth the rainfall was only 24·83 inches, 95 per cent. of the average (26·40 inches). The greatest percentage *excess* was registered in London, the aggregate amount being 38 inches, 156 per cent. of the average annual fall, and at Oxford the rainfall amounted to 142 per cent. of the average. At Greenwich (not shown on the chart) the rainfall for the year was 35·58 inches, being 11·43 inches above the average for sixty years; there were 184 rainy days. The previous largest fall there in this period was 34·01 inches in the year 1852.

SOME of the smaller shell-fish, especially cockles, have recently been found to be grossly contaminated with sewage. These fish form a staple article of diet among the poorer classes, and since they are cooked before consumption, it might be thought that the bacillus of typhoid fever would

be destroyed and the molluscs rendered harmless thereby; but this cooking is a very perfunctory process, and consists in plunging netfuls of the live fish, the shells of which are tightly closed, into a vessel containing boiling water. The immersion of the cold mass immediately lowers the temperature, and when, in the course of two or three minutes, the water begins to boil again, the nets are lifted out. The scalding kills the fish and causes the shells to open, but does not sterilise the contents, and fish that had been kept in typhoid polluted water were found to be swarming with live bacilli after this process of cooking. Prolonged boiling would be effective, but causes the fish to shrivel and spoils them for sale. Dr. Klein suggested that cooking by steam might be found to sterilise efficiently without spoiling the fish as food, and some experiments have recently been carried out for the Fishmongers' Company with a view to test this. Two batches of molluscs were cooked, one for ten minutes and the other for five. The steamer used was a vessel two feet deep, the fish being distributed in three layers on trays, the steam being introduced by a pipe about an inch from the bottom. The results were: ten minutes, mussels spoilt and useless, cockles all right in upper layer, bottom layer overcooked; five minutes, mussels all right, and also two upper layers of cockles, but bottom layer of cockles less satisfactory. The bacterial results were that the cockles proved to be sterile in all cases. The mussels were also sterile, except some in the top layer steamed for five minutes, which still contained some living spores. As a result of these experiments the Fishmongers' Company feels justified in strongly recommending a substitution of steaming for boiling to the trade.

DISCUSSING the subject of nuclear division without cell division, Mr. Ralph Lillie suggests that mitosis is an incidental consequence of the passage of the chromatin into the strongly acid and chromatic phase. This change, he believes, involves the acquisition by the chromatin of a negative charge of considerable potential, as a result of the inductive action of which there ensues a redistribution of the ions in the cytoplasm with the production of certain differences of electrical potential. To these potential differences are due the appearance of the astral radiations and the diminution of surface tension that leads to cleavage (*Biological Bulletin*, vol. iv. No. 4).

IN a paper in the *Technology Quarterly* (vol. xvi. No. 3) Messrs. C. E. A. Winslow and C. P. Nibecker discuss the significance of bacteriological methods in sanitary water analysis. They consider that the real application of chemistry begins where that of bacteriology ends. When pollution is so gross that its existence is obvious and only its amount need be determined, the bacteriological tests will not serve on account of their excessive delicacy. In studying the gross pollution of streams, treatment of trades' wastes, and purification of sewage, the relations of nitrogenous and oxygen compounds are of prime importance, that is, when pollution is to be avoided because the decomposition of chemical substances causes a nuisance, it must be studied by chemical methods. When the danger is that of infection, and arises only from the presence of bacteria, bacteriological methods furnish the best index of pollution. With regard to methods, the authors express a preference for the use of the fermentation tubes, and of gelatin, and of lactose agar, plates.

THE secretary of the Durham College of Science, Newcastle-upon-Tyne, writes to supplement the remarks respecting the conditions on which women can obtain degrees in the University of Durham, contained in an article on the higher education of women published in our issue of December 24, 1903. Residence in Durham is necessary only for women proposing to take a degree in arts of the Durham University; for Durham degrees in science, medicine, &c., attendance at the Durham College of Science and the University of Durham College of Medicine is the qualification, and there are many women undergraduates at these colleges in Newcastle-upon-Tyne.

IN the December number of the *Zoologist* Mr. A. H. Cocks discusses the length of the period of gestation in the badger, which he is inclined to think is nearer a twelvemonth than the four and a half months assigned to it by Mr. Meade-Waldo.

THE homology and classification of the tines developed in the crown of the antlers of the Carpathian red deer form the subject of an article by Dr. E. Botezat in Gegenbaur's *Morphologisches Jahrbuch* (vol. xxxii. part i.). In an appendix the author records the existence of what he regards as two local races of the species, for which the names *Cervus vulgaris campestris* and *C. v. montanus* are proposed. It may be pointed out, in the first place, that *C. vulgaris* is not the name of the red deer, and, in the second place, that *C. v. campestris* is preoccupied by *C. campestris*, one of the names of the South American pampas deer.

Bulletin No. 41 of the entomological division of the U.S. Department of Agriculture is devoted to an account of the life-history of the codling-moth and the damage inflicted by its caterpillar on orchards. The author, Mr. C. B. Simpson, states that this now cosmopolitan insect was introduced into the North-west Pacific States about the year 1880. On account of the genial climate of this new habitat two overlapping annual broods are now produced, and if proper preventive measures are not taken to keep them in check, the entire apple-crop in many districts is liable to damage. The best remedial measures appear to be arsenical spraying and banding, and by these means the damage to the crop in one case has been reduced from between 40 and 60 per cent. to as low as 10 per cent., while it is estimated that by continuing the process for a few years the injury inflicted by this insect might in any locality be reduced from nearly 100 per cent. to 5 or 10 per cent. The annual shrinkage in value of American apple-crops owing to the ravages of this moth has been estimated at 11,000,000 dollars.

THE seas of Japan, Okhotsk, and Bering have been attracting of late a great deal of attention from both Russian and American explorers. M. P. Schmidt gives now, in a recent issue of the *Izvestia* of the Russian Geographical Society (1903, ii.), a short sketch of the physical geography of these seas, with a list of 133 species of fishes found in them, and their distribution, the list being based both on previous research and the author's own collection, which contains 100 species.

THE hydrographic expedition of M. L. S. Berg, which has collected interesting data concerning the present rise of level of Lake Aral, has also studied the temperature, the currents of the lake and its salinity (specific gravity from 1.0076 to 1.0080 in the middle parts, and up to 1.0084 and 1.0090, occasionally 1.0094 in sheltered bays). The plankton is poorer than in European lakes, and during the hot days it keeps at a certain depth, coming to the surface only in the moonlight. M. S. A. Zernoff, who has studied the Aral collections, has found in them quite a number of forms which had only been met with in the Caspian Sea, and had only lately been described by Prof. Sars. The expedition has also collected ants, lizards, and other specimens of interest to naturalists.

The *Century Magazine* for January contains an illustrated article on radium by Prof. E. Merritt, and one on radium and radio-activity by Mme. Curie. The extraction and properties of the new element are also described in the *Strand Magazine*, in the course of an illustrated interview with M. Curie.

The bound volume for 1903 of *Knowledge*, which has now been published, makes a very attractive book. It is profusely illustrated, and, as usual, the astronomical plates are particularly good. The magazine has just been incorporated with the *Illustrated Scientific News*, and the combined journal will be published under the joint title of *Knowledge and Illustrated Scientific News*.

The second part of vol. ii. of "The Fauna and Geography of the Maldive and Laccadive Archipelagoes," being the account of the work carried on and of the collections made by an expedition during the years 1899 and 1900, has been published by the Cambridge University Press. This part, edited by Mr. J. Stanley Gardiner, contains the following three reports:—marine mollusca, by Mr. Edgar A. Smith; the Enteropneusta, by Mr. R. C. Punnett; and marine Crustacea—the spider-crabs (Oxyrhyncha) and the classification and genealogy of the reptant decapods—by Mr. L. A. Borradaile. The third part of vol. ii. is to be published on May 15.

We have received the second series of vol. viii. of the "Proceedings and Transactions of the Royal Society of Canada," and notice that it contains a full account of the twenty-first general meeting held at Toronto in May, 1902. The presidential address, by Sir James A. Grant, K.C.M.G., had for its subject the universities in relation to research, and constitutes the first appendix to the first part of the volume, which includes the *Proceedings*. The second appendix contains reports from twenty-seven associated literary and scientific societies in Canada, some of the reports being in French. Similarly the section of the *Transactions* dealing with French literature, history, and archæology is given in French. Among papers read before the section concerned with the mathematical, physical, and chemical sciences may be mentioned:—On the stresses developed in beams loaded transversely, by Prof. H. T. Bovey, F.R.S.; researches in physical chemistry carried out in the University of Toronto during 1901–2, by Prof. W. L. Miller; on the existence of bodies smaller than atoms, by Prof. Rutherford; on the absolute value of the mechanical equivalent of heat, by Prof. H. T. Barnes; and the specific heats of organic liquids and their heats of solutions in organic solvents, by Dr. J. W. Walker and Dr. J. Henderson. In the section of the geological and biological sciences twelve papers are included, and among them are two by Prof. D. P. Penhallow on *Osmundites skidegatensis* and notes on Cretaceous and Tertiary plants of Canada. Dr. G. F. Matthew contributes notes on Cambrian faunas, and Prof. A. P. Coleman discusses the classification of the Archæan. The volume contains numerous well executed illustrations, and is an excellent witness to the value of the work in science which is being accomplished in Canada.

The determination of the density of chlorine gas is attended with many experimental difficulties, and the figures obtained by different workers vary between 2·448 and 2·491. In the current number of the *Comptes rendus* MM. H. Moissan and Binet du Jassoneix describe their researches on this subject. Three groups of experiments are given, involving seventeen determinations, and the final figure regarded as the most probable is 2·490 at 0° C., a value identical with the figure of Leduc. The chief sources of error to be eliminated are the presence of air in the density flask, the difficulty of completely drying the gas, and the solubility of different gases in liquefied chlorine.

In a recent number of the *Comptes rendus* it is stated by M. Becquerel that when crystals of hexagonal zinc blende are crushed between glass plates they emit a flash of light comparable with that which is produced by the proximity of a radium salt in Crookes's spinthariscope. It is suggested that in the latter case the positively charged α-particles fracture by their impact the surface of the blende, and that the flashes of light observed are thus caused by a mechanical action on the screen.

The origin of natural asphalte or bitumen has given rise to much speculation, and the suggestion has been made that it is produced by the destructive distillation of vegetable remains mixed with organic matter, and especially with fish. Another possible explanation is suggested by the production of an artificial asphalte by heating natural petroleum with sulphur. The series of paraffins is not affected by this treatment, but the naphthenes which are present in the petroleum undergo condensation and give rise to bodies which may be regarded as typical constituents of asphalte. Two of these, prepared by the action of sulphur on acenaphthene, $C_{10}H_6\langle\begin{smallmatrix}CH_2\\ |\\ CH_2\end{smallmatrix}$, have recently been described by Karl Dziewoński in the *Berichte*. The first is a hydrocarbon, $C_{36}H_{18}$ (trinaphthylene benzene), melting at 387° C., which contains no less than ten independent ring systems, and is therefore named decacyclene, whilst the second is a sulphur-compound, $C_{24}H_{12}S$ (dinaphthylenethiophen), melting at 278° C.

The additions to the Zoological Society's Gardens during the past week include a Mozambique Monkey (*Cercopithecus pygerythrus*) from East Africa, presented by Lady Amherst; a Patas Monkey (*Cercopithecus patas*) from West Africa, presented by Mr. F. A. Knowles; a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, presented by Mr. G. A. Hanton; a Black-backed Jackal (*Canis mesomelas*) from South Africa, presented by Captain Moseley; a Hairy-rumped Agouti (*Dasyprocta prymnolopha*) from Central America, presented by Mr. John Gordon; two Ring-tailed Coatis (*Nasua rufa*) from South America, presented respectively by Mr. H. Everest and Mr. D. F. Mackenzie; a Water Rail (*Rallus aquaticus*), British, presented by Mr. F. W. Pizzey; a Californian Sea Lion (*Otaria californiana*) from the North Pacific Ocean, seven Indian Fruit Bats (*Pteropus medius*) from India, deposited.

OUR ASTRONOMICAL COLUMN.

Astronomical Calendars for 1904.—The "Annuaire du Bureau des Longitudes" for 1904 contains more than 700 pages of useful tables and formulæ, astronomical and physical, including lucid explanations of such matters as the several different calendars, the tides, &c. A new arrangement is inaugurated in this year's publication; instead of giving the customary complete set of tables, &c., only those relating to astronomy, physics, and chemistry are included, and it is proposed to omit the chemistry and physics next year, giving instead full sets of tables relating to general geography, meteorology, and statistics. This alternation will be continued in future "Annuaires."

The "Annuaire astronomique et météorologique," compiled by M. Camille Flammarion, attains its fortieth year of publication in the issue for 1904. It gives a complete account of the astronomical occurrences due this year, and a useful review of the astronomical and meteorological

phenomena of recent years. The current issue contains many illustrations, among which are some good reproductions of photographs and drawings of sun-spots, comets, and planetary features observed during 1903. The charts of the sky and the particulars of interesting phenomena, which are given for each month, will be found very useful by all who are engaged in practical astronomy. The "Annuaire" is published by M. Ernest Flammarion, 26 Rue Racine, Paris, at 1.50 francs (about 1s. 3d.).

The card calendar issued by Mr. Arthur Mee, of Llanishen, under the title "The Heavens at a Glance" contains a very complete set of the tables and a great deal of the information required by an amateur practical astronomer. Being printed on a single stiff card, suitable for hanging on the observatory wall, it is exceedingly handy to use as a source of reference for current astronomical occurrences. Amongst other information the card contains a list of the principal meteor showers, with concise instructions to observers, ephemerides of the planets and lists of double stars, variables and nebulæ. It may be obtained from Mr. Mee, at the above address, for 7d. post free.

THE VARIABLE STAR 1921, W AURIGÆ.—In No. 5, vol. xviii., of the *Astrophysical Journal*, Mr. J. A. Parkhurst, of the Yerkes Observatory, gives the details and results of a series of observations of the variable star W Aurigæ, made by him during the period December, 1898–March, 1903. He determined the position of the variable (for 1900) as R.A. = 5h. 20m. 8·6s., $\delta = +36° 48' 53''$, and found that the magnitude varied from 9·3 at maximum to 13·8 at minimum. The strong colour of this variable is indicated by the fact that when the visual magnitude was 9·5 the photographic magnitude was only 10·9.

The variations are best represented, according to the curves which Mr. Parkhurst has plotted from his observations, by the following elements:—

Max. = J.D. 2414648 + 276 E.
or December 24, 1898 + 276 E.,

the interval, M–m, being 113 days.

LIGHT ECONOMY IN SPECTRUM PHOTOGRAPHY.—In a paper communicated to the current number of the *Astrophysical Journal*, Mr. J. A. Humphreys describes a number of arrangements used by him in photographing spectra for utilising to the full the light obtained from the light source under examination. He has found that the most generally convenient and effective arrangement, when terrestrial light sources are being used, is to place a spherical reflector behind the source so that the focus of the reflected light coincides with the origin. In this way both the reflected and direct light are utilised, and are together focused on the slit by an ordinary condenser. Comparison photographs, which are reproduced in the article, show that the light reflected through the source suffers but little from absorption, and that the net result of using this arrangement is to obtain lines which would otherwise be too weak to photograph, and to strengthen the weaker lines.

Another method, which may be used with any source when a grating is used as analyser, is to place a pair of inclined plane reflectors between the slit and the grating so that the rays from the top and bottom of the slit are reflected on to the centre of the grating, thereby condensing the light from the whole length of the slit into a narrower plane, and so obtaining a stronger spectrum. In another, but somewhat similar, form, the two plane reflectors are placed near to the photographic plate, so that the parallel rays from the top and bottom of the grating are superimposed upon the rays from the centre. It is found that when long-focus gratings are used the slight lengthening of the path of the rays by reflection does not interfere, practically, with the definition. Many other arrangements, including the use of ellipsoidal and paraboloidal reflectors and cylindrical lenses, are explained and illustrated in Mr. Humphreys's article.

INTENSITY OF THE SUN'S LIGHT.—M. Ch. Fabry has communicated to the Paris Academy of Sciences an interesting paper on the candle-power of the sun's light at sea-level. By an ingenious arrangement, wherein the total solar light is diminished in a known ratio by passage through a slit and then through an ammoniacal solution of copper sulphate, he compared the light with a constant standard light of known candle-power, and, after various corrections, found that at sea-level, with the sun at the zenith, the solar light would be 100,000 times more intense than that produced by a decimal candle at a distance of 1 metre. Supposing that the intensity of the light emitted by different parts of the apparent solar surface is the same, this result shows that the intensity of the light received—after atmospheric absorption—from 1 square mm. of the solar disc is equivalent to 1800 candle-power, as compared with 150–200 candle-power per square mm. emitted by the positive pole of the electric arc.

Taking the amount of heat received per minute from 1 square cm. of the solar surface as 1·5 calories, M. Fabry calculates that the energy consumed per candle-power is about 0·12 watt, but, as the invisible heat rays suffer more by atmospheric absorption, the actual amount of energy used up is probably between 0·15 and 0·2 watt per candle (*Comptes rendus*, No. 23, vol. cxxxvii.).

PRIZES PROPOSED BY THE PARIS ACADEMY OF SCIENCES FOR 1904.

THE following subjects for prizes are proposed for the year 1904 by the Paris Academy of Sciences:—

In geometry, the grand prize for mathematical science (3000 francs), the subject proposed being to perfect, in some important point, the study of the convergence of continued algebraical fractions; the Bordin prize (3000 francs), to develop and perfect the theory of surfaces applicable to the paraboloid of revolution; the Vaillant prize (4000 francs), to develop and study all displacements of an invariable figure in which different points of the figure describe spherical curves; the Francœur prize (1000 francs) and the Poncelet prize (2000 francs), for discoveries useful to the progress of pure and applied mathematics.

In mechanics, the extraordinary prize of 6000 francs, to recompense progress in the direction of increasing the efficiency of the French naval forces; a Montyon prize (700 francs), for the improvement or invention of instruments useful to the progress of agriculture, or the mechanical arts or sciences; and the Plumey prize (2500 francs), for an improvement or invention relating to steam navigation.

In astronomy, the Lalande prize (540 francs), for the most interesting observation or memoir dealing with astronomy; the Valz prize (460 francs), for the most interesting observation made during the current year; and the Janssen prize, a gold medal, for an important work on physical astronomy.

In geography and navigation, the Binoux prize (2000 francs), for a work dealing with either of these subjects.

In physics, the Hébert prize (1000 francs), for the best treatise or discovery useful in the practical application of electricity; the Hughes prize (2500 francs), for work contributing to the progress of physics; and the Kastner-Boursault prize (2000 francs), for the application of electricity to the arts, industry, or commerce.

In statistics, a Montyon prize (500 francs), for the best study in French statistics.

In chemistry, the Jecker prize (10,000 francs), for work in organic chemistry.

In physical geography, the Gay prize (1500 francs), for a study of the existing variations in the relative levels of land and sea, by means of precise observations, pursued over a fixed portion of the coasts of Europe or North America.

In botany, the Desmazières prize (1600 francs), for a work on the cryptogams; the Montagne prize (1500 francs), for work on the anatomy, physiology, development or description of the lower cryptogams; the de la Fons-Mélicocq prize (900 francs), for the best botanical work dealing with the north of France; and the Thore prize (200 francs), for the best work on the cellular cryptogams of Europe.

In anatomy and zoology, the Savigny prize (1300 francs), for the assistance of young zoologists making a special study of the invertebrates of Egypt and Syria; and the Thore prize (200 francs), for a work on the anatomy of a European species of insect.

In medicine and surgery, a Montyon prize (three prizes of 2500 francs, three mentions of 1500 francs), for discoveries useful in the art of healing; the Barbier prize (2000 francs), for a valuable discovery in the surgical, medical or pharma-

-ceutical sciences, or in botany in relation to medicine; the Bréant prize (100,000 francs), for the discovery of a specific cure for Asiatic cholera, or for the discovery of its cause, such that the epidemic can be suppressed. If neither of these be forthcoming, the interest on the capital sum will be given for a rigorous demonstration of the presence in the air of substances playing a part in the propagation of epidemic diseases. The Godard prize (1000 francs), for a memoir on the anatomy, physiology, or pathology of the genito-urinary organs; the Lallemand prize (1800 francs), for the encouragement of work relating to the nervous system; the Baron Larrey prize (750 francs), for a work on military medicine, surgery or hygiene; the Bellion prize (1400 francs) and the Mège prize (10,000 francs), for an essay on the causes which have retarded or favoured the progress of medicine from antiquity to the present day.

In physiology, a Montyon prize (750 francs), for a work in experimental physiology; the Philipeaux prize (900 francs); the Pourat prize (1000 francs), for a study of the physical and chemical changes in respiration induced by high altitudes; and the Martin-Damourette prize (1400 francs), for a work on therapeutical physiology.

Among the general prizes are the Arago medal; the Lavoisier medal and the Berthelot medal; the Montyon prizes (unhealthy trades, 2500 francs and 1500 francs), for a discovery ameliorating the condition of an unhealthy trade; the Wilde prizes (4000 francs, or two of 2000 francs), for a discovery in astronomy, physics, mineralogy, geology or experimental mechanics; the Tchihatchef prize (3000 francs), for exploration in Asia; the Leconte prize (50,000 francs), for a capital discovery in mathematics, physics, chemistry, natural history or medicine; the Jean-Jacques Berger prize (15,000 francs), for a work on Paris; the Delalande-Guérineau prize (1000 francs); the Jerome Ponti prize (3500 francs); the Houllevique prize (5000 francs); the Cahours prize (3000 francs), for researches in chemistry; the Saintour prize (3000 francs); the Trémont prize (3000 francs); the Gegner prize (3800 francs); and the Lannelongue prize (1200 francs).

Among these, the prizes bearing the names of Lalande, Desmazières, Lavoisier, Wilde, Tchihatchef, and Leconte will be awarded without distinction of nationality.

RESEARCH GRANTS OF THE CARNEGIE INSTITUTION.

A LIST of the grants in aid of scientific investigations made by the Carnegie Institution during the fiscal year 1903 is given below. The amount set apart as grants for research during that period was 40,000*l*. From the beginning of the Institution to the end of October, 1903, the number of applications for grants was 1042, and the total sum asked for by the 406 applicants who stated the amount desired was more than 440,000*l*. In addition, the advisory committees recommended grants amounting to 182,300*l*., so that the total sum asked for was about 622,300*l*. It will be evident from this that the present income of the Carnegie Institution can only provide for a small part of the grants requested. The grants made are as follows:—

Anthropology.—For ethnological investigation among the Pawnees, Dr. G. A. Dorsey, Field Columbian Museum, Chicago, Ill., 500*l*.; for obtaining evidence relative to the early history of man in America, Dr. Wm. H. Holmes, director Bureau of American Ethnology, Washington, D.C., 400*l*.; to investigate the precious stones and minerals used in ancient Babylonia in connection with the investigation of Mr. William Hayes Ward, Mr. George F. Kunz, New York City, 100*l*.; for study of oriental art recorded on seals, &c., from western Asia, Dr. William Hayes Ward, New York City, 300*l*.

Astronomy.—For astronomical observations and computations, Prof. Lewis Boss, Dudley Observatory, Albany, N.Y., 1000*l*.; for investigating proposal for a southern and a solar observatory, Profs. Boss, Hale and Campbell, 1000*l*.; for pay of assistants to take part in researches at the Lick Observatory, Prof. W. W. Campbell, Lick Observatory, Mt. Hamilton, Cal., 800*l*.; for a new reduction of Piazzi's star observations, Prof. Herman S. Davis, Gaithersburg, Md., 100*l*.; for measurements of stellar parallaxes, solar photographs, &c., Prof. George E. Hale, Yerkes Observatory, Williams Bay, Wis., 800*l*.; for determining the elements of the moon's motion and testing the law of gravity, Prof. Simon Newcomb, Washington, D.C., 600*l*.; for study of the astronomical photographs in the collection of Harvard University, Prof. E. C. Pickering, Harvard University, Cambridge, Mass., 500*l*.; for pay of two assistants to observe variable stars, Prof. Wm. M. Reed, Princeton Observatory, Princeton, N.J., 200*l*.; for measurement of astronomical photographs, &c., Miss Mary W. Whitney, Vassar College, Poughkeepsie, N.Y., 200*l*.

Bibliography.—For preparing and publishing the "Index Medicus," Dr. Robert Fletcher, Army Medical Museum, Washington, D.C., 2000*l*.; for preparing and publishing a "Handbook of Learned Societies," Mr. Herbert Putnam, Librarian of Congress, Washington, D.C., 1000*l*.

Botany.—For investigation of plant hybrids, Mr. W. A. Cannon, New York Botanical Garden, N.Y., 100*l*.; for study of types of water-lilies in European herbaria, Mr. H. S. Conard, University of Pennsylvania, Philadelphia, 60*l*.; Desert Botanical Laboratory (Mr. F. V. Coville and Mr. D. T. MacDougal, Washington, D.C.), 1600*l*.; researches on the cytological relations of the Amœbæ, Acrasieæ and Myxomycetes, Mr. E. W. Olive, Crawfordsville, Ind., 200*l*.; for preliminary studies on the Philippine flora, Dr. Janet Perkins, working at the Royal Botanical Gardens, Berlin, Germany, 380*l*.

Chemistry.—For a systematic chemical study of alloys, beginning with the bronzes and brasses, Prof. W. D. Bancroft, Cornell University, Ithaca, N.Y., 100*l*.; for investigation of the rare earths, Prof. L. M. Dennis, Cornell University, Ithaca, N.Y., 200*l*.; for investigations in physical chemistry, Prof. H. C. Jones, Johns Hopkins University, Baltimore, Md., 200*l*.; for researches on osmotic pressure, Prof. H. N. Morse, Johns Hopkins University, Baltimore, Md., 300*l*.; for certain chemical investigations, Prof. A. A. Noyes, Massachusetts Institute of Technology, Boston, Mass., 400*l*.; for investigation of values of atomic weights, &c., Prof. Theo. W. Richards, Harvard University, 500*l*.; for continuing investigations on the derivatives of camphor and allied bodies, Mr. J. Bishop Tingle, Illinois College, Jacksonville, Ill., 100*l*.

Engineering.—For experiments on ship resistance and propulsion, Prof. W. F. Durand, Cornell University, Ithaca, N.Y., 824*l*.; for study of aluminium bronzes, Mr. Leonard Waldo, New York City, 900*l*.

Exploration.—For preliminary examination of the trans-Caspian region, Mr. Raphael Pumpelly, Newport, R.I., 1300*l*.

Geophysics.—For investigating the flow of rocks, Prof. Frank D. Adams, McGill University, Montreal, 500*l*.; for investigating the subject of geophysical research, &c., Prof. C. R. Van Hise, University of Wisconsin, Madison, Wis., 500*l*.

Geology.—For study of the fundamental principles of geology, Prof. T. C. Chamberlin, University of Chicago, Chicago, Ill., 1200*l*.; for geological exploration in eastern China, Mr. Bailey Willis, U.S. Geological Survey, Washington, D.C., 2400*l*.

History.—For an examination of the historical archives of Washington, Mr. Worthington C. Ford, Library of Congress, Washington, D.C., 400*l*.

Palaeontology.—For continuation of work on the morphology of Permian reptiles, Prof. E. C. Case, State Normal School, Milwaukee, Wis., 100*l*.; for monographing the fossil Chelonia of North America, Dr. O. P. Hay, American Museum of Natural History, 140*l*.; for continuation of his researches on living and fossil cycads, Dr. G. R. Wieland, Yale University, New Haven, Conn., 300*l*.; for preparing a monograph on the Plesiosaurian group, Prof. S. W. Williston, University of Chicago, Chicago, Ill., 160*l*.

Physics.—For study of certain arc spectra, Prof. Henry Crew, Evanston, Ill., 200*l*.; for aid in ruling diffraction gratings, Prof. A. A. Michelson, University of Chicago, Ill., 300*l*.; for experiments on the magnetic effect of electrical convection, Dr. Harold Pender, Johns Hopkins University, Baltimore, Md., 150*l*.; for research, chiefly on the theory of light, Prof. R. W. Wood, Johns Hopkins University, Baltimore, Md., 200*l*.

Physiology.—For experiments in nutrition, Prof. W. O. Atwater, Wesleyan University, Middletown, Conn., 1000*l.*; for preparing report on the physiology of nutrition, Dr. Arthur Gamgee, Montreux, Switzerland, 1300*l.*

Psychology.—For certain investigations on the anthropology of childhood, Dr. G. Stanley Hall, Clark University, Worcester, Mass., 400*l.*; for researches in experimental phonetics, Prof. E. W. Scripture, Yale University, New Haven, Conn., 320*l.*

Zoology.—For determining the laws of variation and inheritance of certain Lepidoptera, Dr. H. E. Crampton, Columbia University, New York, 50*l.*; for investigation of recent and fossil corals, Dr. J. E. Duerden, Chapel Hill, N.C., 200*l.*; for investigating the blind fishes of Cuba, Dr. C. H. Eigenmann, Indiana University, Bloomington, Ind., 200*l.*; for preparing manuscript and illustrations for a monograph on American mosquitoes, Dr. L. O. Howard, Department of Agriculture, Washington, D.C., 400*l.*; for experiments on the behaviour of lower animals, Dr. H. S. Jennings, University of Michigan, Ann Arbor, Mich., 50*l.*; to making a comparative study of the spermatogenesis of insects and other classes of arthropods, and if possible to determine the specific functions of the different chromosomes, Prof. C. E. McClung, Kansas University, Lawrence, Kans., 100*l.*; for investigations in experimental embryology, &c., in Naples, Dr. E. B. Wilson, Columbia University, New York, 200*l.*; for morphology and classification of deep sea sponges, Prof. H. V. Wilson, University of North Carolina, Chapel Hill, 200*l.*; for maintenance of twenty tables, Marine Biological Laboratory, Woods Hole, Mass., 2000*l.*; for maintenance of two tables, Marine Biological Station, Naples, Italy, 200*l.*

SURVEY OF SCOTTISH LAKES.

READERS of NATURE are aware that in the year 1896 Sir John Murray and the late Mr. Fred. P. Pullar commenced to carry out a bathymetrical survey of the fresh-water lochs of Scotland, but the work was brought to a standstill in February, 1901, owing to the tragic death of the younger collaborator, who heroically lost his life in attempting to save others in an ice accident on Airthrey Loch, near Bridge of Allan. As a memorial to this talented young man, his father, Mr. Laurence Pullar, and Sir John Murray resolved to complete this important piece of work at their joint expense, and in the spring of 1902 the survey was resumed under the personal supervision of Sir John Murray, with the assistance of a staff of young scientific men.[1]

During the season of 1902 one hundred and fifty-five Scottish lakes were completely surveyed, and during the past season two hundred and thirty-one, making a total of three hundred and eighty-six of the Scottish fresh-water lochs completed, including all the larger and more important ones. There still remain, however, a good many small and outlying lochs to be surveyed, but it is anticipated that early next season (1904) the actual work of sounding the Scottish fresh-water lochs so far as practicable will be completed. The preparation of the maps for the engraver has been going on continuously, and the publication of the results of the survey has already been commenced in the *Geographical Journal* and the *Scottish Geographical Magazine.*

In continuation of the work of Sir John Murray and the late Mr. Pullar among the lochs of the Forth and Tay basins, the staff of the Lake Survey commenced operations early in 1902 in the northern portion of the Tay basin, and after surveying the principal lochs in that neighbourhood moved northwards and westwards through Perthshire, Inverness-shire, Argyllshire, Ross-shire, Sutherlandshire, and Caithness-shire, sounding all the more important lochs, like Lochs Tay, Rannoch, Treig, Laggan, Arkaig, Shiel, Morar, Maree, Fannich, Shin, Assynt, More, Naver, Loyal, Hope, and many smaller ones. In the spring of 1903 a start was made with the lochs of the Caledonian Canal (Ness and Lochy) and of the surrounding district, then the staff moved southwards to Loch Awe and Loch Lomond, which were sounded for the sake of comparison with the surveys carried out by the Admiralty in the year 1861. Subsequently the staff was split up into small parties, one party proceeding to the south of Scotland to survey Lochs Doon, Ken, Dee, &c., a second party proceeding to Lewis to survey Loch Langavat and other smaller lochs, while a third party proceeded to Orkney and Shetland to survey Lochs Harray and Stenness, and the numerous small lochs in those islands.

In addition to the routine sounding work, continuous observations of a varied description have been carried out on Loch Ness throughout the past season. In order to study the seiches in Loch Ness, a limnograph, constructed in Geneva under the supervision of Dr. Ed. Sarasin, was set up in the grounds of St. Benedict's Monastery at Fort Augustus (by kind permission of the Lord Abbot), and has been in charge of Mr. E. M. Wedderburn. The records obtained are now being studied and classified, and are likely to lead to interesting results; uninodal, binodal, and multinodal seiches have been recognised, and their duration, periodicity, and amplitude determined.

Continuous observations of the temperature of the water at different depths in Loch Ness have also been carried on by Sir John Murray, Mr. Watson, and other members of the staff since July. The temperature changes have been studied systematically—first, by means of platinum resistance thermometers with Callendar's recording apparatus, installed by the Cambridge Scientific Instrument Co., at a cost of several hundred pounds, from a yacht anchored in 300 feet of water off Fort Augustus, and connected with the shore by an electric cable; seconu, by means of ordinary reversing thermometers at Fort Augustus and from a steam yacht, which during several weeks made numerous cruises throughout the length of the loch. Difficulties have cropped up with reference to the working of the electrical thermometers, but the observations made thus far have shown that the waters in Loch Ness are in constant motion, even down as far as 300 to 400 feet. The motion of the upper waters in Scottish lochs has been already studied by Sir John Murray, who advanced the theory that a wind blows the surface water before it, and so causes a slope of the upper isothermals down towards the lee shore. The investigations in Loch Ness confirm this theory, whilst adding some restrictions for this particular case. But the chief interest attaches to the study of the motion of the deeper isotherms, which have never before been studied with care. These isotherms have been found to be swinging in a periodic fashion, with a natural period of about three days. It is supposed that we have here an internal seiche, with the separating surface determined by the greatest change of temperature with depth, the restoring force being given by the difference of density between the warmer upper and the colder deeper waters. The investigations indicate that this internal seiche is started by gales or winds of a strength above the average.

Many biological observations have also been made in Loch Ness and neighbouring lochs by Mr. James Murray, Mr. Scourfield and others, by means of various kinds of townets and drag-nets, with the view of obtaining some insight into the relation between the habits and distribution of the different planktonic and benthonic organisms and the varying physical conditions.

All these limnological investigations have been carried out under the immediate superintendence of Sir John Murray, who took up residence at Fort Augustus from the beginning of July until the end of October, and arrangements have been made for the continuance of the temperature and seiche observations under the charge of Mr. Watson, and of the biological observations under the charge of Mr. James Murray, throughout the winter.

[1] The field staff consisted of Mr. T. N. Johnston, first assistant and zoologist; Mr. James Parsons, chemist; Mr. T. R. H Garrett, geologist; Mr. John Hewitt, zoologist; Mr. James Murray, assistant zoologist: and the following gentlemen took part in the field work for longer or shorter periods during the summer of 1902, viz. Mr. R. M. Clark, Dr. J. Sutherland Black, Sir John Jackson, Mr. D C McIntosh, Mr. James Walker, and Mr. D. J. Scourfield. After the completion of the first season's work, Mr. Parsons and Mr. Garrett received appointments in Ceylon and Borneo respectively, and their places on the staff were taken by Mr. R. B. Young and Mr. R. C. Marshall; in addition, Mr. E. R. Watson and Mr. E. M. Wedderburn joined the staff early in 1903, and in July, when Mr. Young left to take up an appointment in the South African College, Mr. J. H. M. Wedderburn took his place on the staff. The office work in Edinburgh is in charge of Mr. James Chumley, secretary and subeditor, with the assistance of Mr. Robert Dykes.

THE SENESCENCE OF ORGANS AND ITS INFLUENCE ON PATHOLOGICAL PHENOMENA.

A PAPER by Prof. R. Wiedersheim on the senescence of organs in the phylogenetic history of man and its influence on morbid phenomena has been published in the *Politisch-anthropologischen Revue*, II. Jahrgang, Heft 6 (Thuringische Verlags-Anstalt Eisenach und Leipzig).

In emphasising the fact that in many cases organs, or tissues, which are spoken of as vestigial, and are considered to be functionless, may in reality play an important part in the physiological balance of the organism, the author points out that the same is true not only of those parts which are degenerating, but also of those which, though at present of comparatively little importance in the ordinary sense, are in a state of progressive development, or have undergone a change of function.

Pathologists have long recognised the fact that tissues which have been arrested in development during ontogeny are likely at certain times to give rise to pathological conditions, and Prof. Wiedersheim maintains that one is justified in speaking of the old age and senile degeneration of organs, or tissues, in a phylogenetic sense, just as one uses these terms in the case of individuals. He believes that in many cases there is evidence that certain phylogenetic stages in the development of organs, or tissues, are less resistant than others to pathological changes, just as in the individual the tissues are less able, at certain ages, to resist baneful influences arising within or outside the body. A large number of examples are given to show that organs phylogenetically very old are often prone to various diseases, such as carcinoma, &c.

The question is discussed as to why organs which have reached this form of old age are retained, and the conclusion is arrived at that they have no selection-value, and therefore do not affect the preservation of the species.

Organs, or parts of organs, which are in this sense phylogenetically aged are compared by the author to the aged members of a community, who may roughly be divided into two classes—one containing those who conform to the arrangements made for them by the community and take little or no interest in what is going on, the other containing those aggressive individuals who oppose improvements and progress. Society experiences trouble from the members of this latter class, and similarly those phylogenetically aged structures which we have inherited from our ancestors may, if they retain sufficient vitality, seriously affect the vital equilibrium of our bodies.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

PROF. PAGEL has resigned his chair of naval architecture in the Berlin Technical School, on his appointment to the post of technical director of the German Lloyd.

DR. H. GRASSMAN has been appointed professor of mathematics at Halle, Mr. F. C. M. Störmer professor of pure mathematics in the University of Christiania, and Dr. H. Veillon professor of physics and chemistry at Basle.

A COURSE of ten lectures on enzymes and their actions will be delivered by Dr. W. M. Bayliss, F.R.S., at University College, London, on Wednesdays at 5 p.m., beginning Wednesday, January 13. The lectures are open to all internal students of the university without fee, as well as to qualified medical men, on presentation of their cards.

A MEETING of medical graduates of Oxford engaged in teaching in London was held on Tuesday to consider the vacancy in the regius professorship at Oxford caused by the resignation of Sir John Burdon Sanderson. The chair was taken by Sir William Church, president of the Royal College of Physicians. It has been suggested that the present reader in pathology should be appointed regius professor of medicine, so that the emoluments of the chair of medicine might be made to supplement the income of the reader in pathology. A statement setting forth reasons against this proposal has been sent to all medical graduates of Oxford for signature, and the following resolutions were passed at Tuesday's meeting:—"That in the opinion of this meeting the regius professor of medicine should be a physician who is representative of medicine in its widest sense." "That it would be detrimental to the best interests of medicine in Oxford if the regius professorship were converted into a professorship of any one branch of medical study."

SCIENCE does not occupy a prominent place in the new educational monthly entitled *School*, the first number of which has just been received from Mr. John Murray, but the contents include much matter which should stimulate interest in education as a whole. In summing up his impressions of American education, obtained during the recent visit of the Mosely Commission, the Rev. T. L. Papillon remarks, "what has struck me most in the little that I have been able to see of American education is first of all the attitude of the whole people towards public education, and their recognition of it as a prime necessity of national life, for which hardly any expenditure can be too great; next its eminent practical and popular character." Lord Avebury contributes some early recollections, including his Eton days, when the whole course of instruction consisted of Latin and Greek, with one lesson a week in geography. "Neither arithmetic, modern languages, science nor drawing were regarded as essential portions of education, and they did not enter into the school course." There are also articles, among others, on the late Mr. Herbert Spencer and on the education of the engineer.

A SUBJECT which deserves careful and sympathetic investigation by the Board of Education was brought before public notice in the *Morning Post* of December 29, 1903, and dealt with in a leading article. As will be within the knowledge of most readers of NATURE, there are at the Royal Colleges of Science of London and Dublin two classes of students, those, namely, who pay fees, and those who hold scholarships, studentships, or exhibitions, and have been selected by the Board of Education by competition or otherwise. Many of these "Government" students hold what are called national science scholarships. Until 1901 these national scholars received during the forty weeks in the academic year an allowance of thirty shillings a week, out of which the great majority of them had to find board, lodging, clothes, books and apparatus—for the national scholars, of whom there are sixty, come almost exclusively from the lower middle classes, and are without any private means. Since 1901, this weekly allowance has been reduced to twenty-five shillings a week. This reduction in value of the national scholarships has, very naturally, given rise to much dissatisfaction, and early last year a petition, drawn up by the Students' Union, was signed by all the national scholars in the Royal College of Science, London, and on the advice of the council of the college was forwarded to the Board of Education. A reply to this petition, signed by Mr. F. G. Ogilvie, was received in due course, and it contains the statement that "in fixing the present rates the Board were of opinion that an allowance of *1l. 5s.* per week would be a sufficient supplement to the resources of the students to whom scholarships were awarded to enable them to devote their whole time and energy to the prosecution of their studies during the period over which the courses at the Royal College of Science would extend." The suggestion that national scholars have private resources upon which they can draw is certainly based upon a misapprehension; for only very rarely do such scholars receive any allowance from home or friends, and we believe that all the national scholars at present at the Royal College of Science are without private means. There can be no doubt that for a student to live within a reasonable distance of the college at South Kensington, and with comforts sufficient to enable him to perform his work properly, he must spend more than twenty-five shillings a week. The attempt to work earnestly and for long hours every day, and at the same time to pay his way on the amount of his present allowance, must lead to needless irritation, and in many cases to real hardship and permanent injury to health. The only satisfactory solution of the difficulty which has arisen would seem to be the establishment of suitable halls of residence for all scholarship holders, in which that corporate life which is so important a part of university life may be enjoyed by these young men who are studying science for their own and their country's benefit.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 19, 1903.—"On the Nematocysts of Æolids." By G. H. **Grosvenor,** New College, Oxford. Communicated by Prof. W. F. R. Weldon, F.R.S.

The nematocysts of æolids were discovered by Alder and Hancock in 1843. As early as 1858 Strethill Wright communicated to the Royal Phys. Soc. of Edinburgh the results of some observations which seemed to prove that these nematocysts were not developed in the body of the æolid, but derived from its cœlenterate prey. This paper, though republished in the *Microscopical Journal* four years later, seems to have been entirely overlooked, and the nematocysts of nudibranchs have been generally supposed to be developed *in situ*, and have often been quoted as an inexplicable example of homoplasy or even as evidence of a close relationship between Mollusca and cœlenterates. C. O. Glaser has, however, recently supported the opposite view.

The evidence brought forward in the present paper in support of Strethill Wright's view is as follows:—

(1) Not only are the nematocysts of æolids and Cœlenterata identical in plan and in mode of discharge, but each of several distinct types occurs in both groups.

(2) The nematocysts of æolids vary from individual to individual within the species, and even in the same individual there may be nematocysts characteristic of two or more distinct genera or families of cœlenterates.

(3) Whenever it is known on what cœlenterate an æolid has recently fed, the nematocysts of the two are found to be identical. Also the nematocysts in the fæces are always indistinguishable from one of the kinds, at least, in the cnidosac.

(4) Those æolids (Janidæ, Fiona, and *Calma glaucoides*) which are known to feed on non-cœlenterate prey have no nematocysts.

(5) Nematocysts and other indigestible bodies have been observed to pass through the ciliated canal from the cavity of the gastric gland into the cnidosac.

(6) Strethill Wright's most conclusive evidence was derived from an experiment of feeding an æolid on a hydroid with nematocysts different from those in the cnidosacs of the æolid. This experiment has been repeated several times, always with the result that the new nematocysts very soon appeared in the cnidosacs of the æolid. In one case three specimens of *Rizzolia peregrina*, with only small pip-shaped nematocysts (6·5 μ) in their cnidosacs, were fed on *Pennaria Cavolinii*, a hydroid with very distinct ovoid nematocysts of two sizes (25 μ and 7 μ). After about a month of this diet the pip-shaped nematocysts were almost entirely replaced by those of Pennaria. These latter were enclosed in cnidocysts in the ordinary way.

Though the nematocysts of æolids are derived from their food, they discharge the threads on extrusion from the cerata into sea-water, and there can be little doubt that they are used as weapons of defence. But an important, and probably the original function of the terminal openings of the cerata is the elimination of the indigestible nematocysts, which, on account of the diffuse character of the digestive system, cannot easily be got rid of through the anus only.

The fact of their discharge when extruded naked into the sea-water from the cnidosacs of an æolid proves that nematocysts work without the intervention of living protoplasm. A study of the conditions of discharge of nematocysts in cœlenterates and æolids, and of their behaviour in various solutions, leads to the conclusion that we have to do with a phenomenon of osmosis.

In the development of the cnidocysts two kinds of cells take part; one, the so-called "cnidoblast," ingests and arranges the nematocysts, while others lying between adjacent cnidocysts take part in the secretion of the membranous walls. Both kinds degenerate in the fully formed cnidocyst.

December 13, 1903.—"Preliminary Note on the Resistance to Heat of *B. anthracis.*" By A. **Mallock,** F.R.S., and Lieut.-Colonel A. M. **Davies.**

This paper describes a series of experiments made by heating water infected with anthrax to various temperatures for various times, in order to determine the temperature and time necessary for the destruction of the spores.

The infected water was sealed in glass tubes and heated in steam in an apparatus which was designed so that any desired temperature could be maintained and simultaneously recorded.

The highest temperature employed was 120° C. and the lowest 99°.

The longest time for which the temperature was maintained was twenty minutes, and the shortest twenty seconds.

From statements made by good authorities as to the great heat resisting power of the spores of anthrax, it was expected that the temperature required to destroy the spores, when expressed as a function of the time for which the temperature had to be maintained, would form a curve, the temperature decreasing as the time of its application increased.

The authors, however, found that out of 95 experiments in which the tubes were heated to 100° C. or more, in 81 all life was destroyed, and out of the remaining 14 experiments, in which some growth took place after cultivation in broth, 12 had become contaminated. After heating 18 experiments were made at temperatures between 99° C. and 100° C. In 5 of these experiments some growth occurred after cultivation, 4 of these being found contaminated.

The conclusion arrived at is that when anthrax spores are heated in water to 100° C. or more, even for twenty or thirty seconds, their destruction is almost certain.

Chemical Society, December 16, 1903.—Prof. W. A. Tilden, F.R.S., president, in the chair.—The following papers were read:—The relative strengths of the alkaline hydroxides and of ammonia as measured by their action on cotarnine, by Messrs. **Dobbie, Lauder** and **Tinkler.** When aqueous solutions of cotarnine are treated with alkaline hydroxides or ammonia the alkaloid is changed from the "ammonium hydroxide" form to the "carbinol" form. As solutions of these two forms of cotarnine exhibit very different absorption spectra, it is possible by this means to observe the rates at which this change is brought about by different alkalis. The relative strengths of the alkaline hydroxides as determined by this method are practically identical with those obtained by other physical methods.—Peroxylaminesulphonates and hydroxylaminetrisulphonates, by Mr. T. **Haga.**—An investigation of the sulphazilates and metasulphazilates first obtained by Fremy. Peroxylaminesulphonic acid, by Dr. E. **Divers.** The author shows that the bluish-violet substance produced by the action of sulphur dioxide on sulphuric acid containing nitrososulphuric acid is probably, as has already been asserted by Sabatier, peroxylaminesulphonic acid, the potassium salt of which is described in the preceding paper.—Constitution of nitric peroxide, by Dr. E. **Divers.** It is shown from the results of Haga's investigations that the *mono*-nitric peroxide must have the formula $O:N_2O$, whilst the dinitric peroxide must have the constitution $(NO)_2O_2$.—Halogen derivatives of diphenyl and dihydroxydiphenyl, by Mr. J. C. **Cain.**—Notes on some natural colouring matters, by Messrs. A. G. **Perkin** and E. **Phipps.** The flowers of *Prunus spinosa* contain the two colouring matters quercetin and kampherol. The Japanese dye-stuff "Fukugi" contains a yellow substance closely related to luteolin. A number of derivatives of morin, hesperitin, myricetin and curcumin are also described.—The estimation of methyl alcohol in the presence of ethyl alcohol, by Messrs. T. E. **Thorpe** and J. **Holmes.** The method is based upon the difference in behaviour of these two alcohols towards a mixture of potassium dichromate and sulphuric acid.—Separation and estimation of silver cyanide and silver chloride, by Mr. R. H. A. **Plimmer.** The mixture is treated with boiling dilute nitric acid, and the hydrocyanic acid so liberated distilled off and estimated as silver cyanide.—Estimation of hydroxyl radicles, by Messrs. H. **Hibbert** and J. J. **Sudborough.** A modification of Tschugaeff's method is described.—Diortho-substituted benzoic acids, part v., formation of salts from diortho-substituted benzoic acids and organic bases, by Messrs. J. J. **Sudborough** and W. **Roberts.**—Cis-π-camphanates of *d*- and *l*-hydrindamines, by Prof. F. S. **Kipping.**—Resolution of *dl*-methylhydrindamine, by Mr. G. **Tattersall.**—Isomeric salts of *d*- and

l-methylhydrindamines with *d*-chlorocamphorsulphonic acid, by Mr. G. **Tattersall.**—The four optically isomeric *l*-menthylamines and their salts, by Messrs. F. **Tutin** and F. S. **Kipping.**—Preparation of the tetra-alkyl derivatives of stannimethane, by Messrs. W. J. **Pope** and S. J. **Peachey.** The authors have prepared a number of these derivatives by the interaction of magnesium alkyl haloids with stannic chloride or alkyl derivatives of the latter.—Optically active esters of β-ketonic and β-aldehydic acids, part iv., condensation of aldehydes with menthyl acetoacetate, by Messrs. A. C. O. **Hann** and A. **Lapworth.**—Estimation of the adulterant in citronella oil, by Mr. M. K. **Bamber.**

Geological Society, December 16, 1903.—Sir Archibald Geikie, Sec.R.S., vice-president, in the chair.—The igneous rocks associated with the Carboniferous Limestone of the Bristol district, by Prof. C. Lloyd **Morgan,** F.R.S., and Prof. Sidney H. **Reynolds.** Evidence for the contemporaneous origin of the igneous rocks is given for several localities. At Middle Hope the ejectamenta thin to the east, and lava is only found to the west; at Spring Cove, near Weston-super-Mare, small lapilli were found in the limestone 8 feet above the basalt. At Goblin Combe there is the most characteristic section of ashy beds; the lenticular bands of greenish tuff, the limestone-intercalations, the admixture of lapilli, limestone fragments, and oolitic grains are stamped with the mark of submarine volcanic action; lava closely underlies these breccias and tuffs. There is evidence of only one volcanic episode, which occurred in all cases after the Zaphrentis beds had been laid down, and before the strata characterised by Chonetes and Streptorhynchus were deposited. The lavas are olivine-dolerites or basalts, with phenocrysts of olivine or augite. They are frequently amygdaloidal, and in the variolites highly-altered felspar-phenocrysts occur. The rocks vary in grain. The tuffs are all calcareous, and most are best described as "ashy limestones." The bulk of the lapilli varies from one-hundredth part of the rock to about one-third, and their composition is related to that of the basaltic lavas of the district.—The Rhætic beds of England, by Mr. A. Rendle **Short.** The paper opens with a description of four new exposures of these rocks; one at Redland rests upon Carboniferous Limestone; a second is at Stoke Gifford, with a continuous, well-developed landscape-marble, the insect bed, and no bone bed; a third at Cotham Road (Bristol) yields baryta, celestine, and Naiadita at horizons containing no other fossils; and the fourth, at Aust, has given measurements of the uppermost 13 feet. An account is given of the constituent beds, with reference to the conditions of deposition.

PARIS.

Academy of Sciences, December 28, 1903.—M. Albert Gaudry in the chair.—M. Troost was elected a vice-president for the year 1904.—Researches on the density of chlorine, by MM. H. **Moissan** and Binet **du Jassoneix** (see p. 233).—On some new syntheses effected by means of molecules containing the methylene group associated with one or two negative radicals. The action of epichlorhydrin upon the sodium derivative of acetylacetone, by MM. A. **Haller** and G. **Blanc.** The reaction between epichlorhydrin and sodium acetylacetone is distinguished from the reactions between epichlorhydrin and the sodium derivatives of acetoacetic ester, benzoylacetic ester, and similar compounds by the fact that the chlorine reacts with the sodium, giving rise to products free from chlorine, one of which appears to be $CH_3.C{=}CH—CH_2—CH.CH_2OH$. This changes spontaneously into a ketone, the constitution of which is under examination.—The potash soluble in the water of the soil and its utilisation by plants, by M. Th. **Schlœsing,** jun.—On the first volume of the photographic catalogue of the sky published by M. A. Donner, director of the Observatory of Helsingfors, by M. **Lœwy.**—Remarks by M. R. **Zeiller** on the work of M. Michel Lévy on the fossil flora of the Tonkin Coal-measures.—Remarks by M. Alfred **Picard** on presenting his report on the Exhibition of 1900.—On the scapular and pelvic hands in the chondropterygian fishes, by M. Armand **Sabatier.**—On the limit of the Jurassic and Cretacean in the eastern part of the Pyrenees, and on the existence of two distinct epochs of formation of couzeranite limestones, by MM. Ch. **Depéret** and O. **Mengel.**—On the influence of the depth of immersion of a vessel on the speed, by M. J. A. **Normand.** A mathematical investigation into the relations existing between the weights of coal, engines, and other load, the maximum speed, displacement, and the exponent according to which the velocity varies in the neighbourhood of the maximum power. On a property of functions, by M. H. **Lebesgue.**—On linear partial differential equations, by M. J. **Le Roux.**—The convergence of periodic superposed roots, by M. Paul **Wiernsberger.**—On a new system of road traction called *à propulsion continue*, by M. Charles **Renard.** A description of a method of mechanically transmitting the power of a locomotive to a series of attached vehicles, the whole train forming a kind of articulated locomotive. The advantages gained are great precision in steering round corners, and a reduction in the weight of the locomotive, since the tractive power is not limited, as in the usual type, by the adhesion of its wheels.—New electromechanical arrangements of engagement and gradual change of velocity, by M. Paul **Gasnier.** A method of using an electrically driven motor by which its speed can be gradually varied from nothing to maximum as required.—On the extension of the Clapeyron formula to all indifferent states, by M. L. **Ariès.**—On the luminous intensity of stars and their comparison with the sun, by M. Charles **Fabry.** Measurements made on the intensity of the star Vega, near the zenith, in calm weather and at the sea-level, gave a value equal to a candle at 780 metres distance, or 1.7×10^{-6} candles. A relation between magnitude of a star as usually measured by astronomers and the candle-power is then worked out.—On the difference of temperature of bodies in contact, by M. E. **Rogovsky.**—On sliding discharges, by M. J. **de Kowalski.**—On a diffusiometer, by M. J. **Thovert.** A modification of an instrument previously described, suitable for volatile liquids. The rate of diffusion is measured by the change in the refractive index of the liquid.—On a new method of preparing some anhydrous crystallised fluorides, by M. **Defacqz.** By heating a mixture of calcium chloride and manganese fluoride, the former being in excess, to 1000°–1200°, crystallised calcium fluoride is obtained, either in cubes or octahedra.—Electrical osmosis in liquid ammonia, by M. Marcel **Ascoli.**—On the dissociation of alkaline carbonates, by M. P. **Lebeau.** Sodium carbonate, heated in a vacuum, is appreciably dissociated, the pressure of the carbon dioxide varying from 1 mm. at 700° C. to 41 mm. at 1200° C. Similar measurements were also carried out with the carbonates of potassium, rubidium, and cæsium.—On the α-amino-nitriles, by M. Marcel **Delépine.**—The combination of saccharose with some metallic salts, by M. D. **Gauthier.**—On the transformation of the primary α-glycols into the corresponding aldehydes, by M. **Tiffeneau.** A study of the mechanism of the transformation of $(CH_3).(C_6H_5).C(OH)—CH_2OH$ into $(CH_3).(C_6H_5).CH.CH:O$ by the action of 25 per cent. sulphuric acid.—On the nitric esters of the acid alcohols, by M. H. **Duval.** Description of the preparation and properties of the nitrates of acetoxyacetic, lactic, α-oxybutyric, and glycollic acids.—The action of carbon dioxide upon aqueous solutions of aniline in the presence of nitrites, by M. Louis **Meunier.** An aqueous solution of aniline mixed with sodium nitrite gives diazoamidobenzene in presence of carbonic acid. Silver nitrite with aniline gives the silver salt of diazoamidobenzene. There is no reaction between sodium nitrite and aniline in aqueous solution in the absence of carbon dioxide.—On the retrogradation of starch, by M. L. **Maquenne.**—The preparation of hydrogenated alcohols of the aromatic series, by M. Léon **Brunel.** By the action of hydrogen in the presence of reduced nickel at 170°–200° C., phenol gives cyclohexanol, thymol, hexahydrothymol, and carvacrol hexahydrocarvacrol.—On the oxidation of guaiacum by laccase, by M. Gabriel **Bertrand.**—The development of annual plants: study of the mineral bases, by M. G. **André.**—On the culture of sarrasin in the presence of a mixture of algæ and bacteria, by MM. **Bouilhac** and **Giustiniani.**—The evolution undergone by fishes of the genus Atherina in fresh and brackish water, by M. Louis **Roule.**—New facts on the *n*-rays of physiological origin, by M. Augustin **Charpentier.** The emission of the *n*-rays by living bodies is not peculiar to man; it has been found in rabbits, frogs, and other animals. The most important part of the physiological emission of the *n*-rays

appears to take place in the nervous system, especially in the nerve centres.—The determination of the perceptible minimum and the duration of luminous perception in persons of weak sight, by M. S. **Durand.**—On mountain sickness, by M. **Kronecker.**—On the modifications induced in the respiration by the altitude of Mt. Blanc, by M. J. **Vallot.** The relation between the volume of air respired and the time spent at the summit is shown graphically, and also the variation in the weight of air breathed.—On a relation between the work and the so-called statical work equivalent on the ergograph, by M. Charles **Henry** and Mlle. J. **Ioteyko.**—Researches on the *rôle* of the interstitial gland of the testicle. Experimental compensating hypertrophy, by MM. P. **Ancel** and P. **Bouin.** Phototropism in the higher Artiozoa, by M. Georges **Bohn.**—The action of anethol upon the organism, by MM. E. **Varenne,** J. **Roussel** and L. **Godefroy.** Anethol shows no toxic effects, and may be safely used as a therapeutical agent.—The action of radium upon different tissues, by M. J. **Danysz.** The tissues, and especially the epithelial tissues of young animals, are much more sensitive to the action of radium rays than the tissues of adults.—On a consequence of cross-fertilisation, by M. Leclerc **du Sablon.**—On a true hybrid of chasselas by *Ampelopsis hederacea*, by M. **Grille.**—On the *rôle* of calcium oxalate in the nutrition of plants, by M. **Amar.** The lime (in the form of nitrate) necessary to the constitution of the plant is entirely assimilated up to a certain proportion, depending on the species; above this proportion the excess of lime is eliminated in the form of crystals of calcium oxalate.—On a disease of the leaves of the tobacco plant, by M. H. **Bouygues.**—On the Glacial deposits of the Garonne, by M. L. A. **Fabre.**—The geology of the western Alps, by M. Emile **Haug.**—Contribution to the study of the basaltic rocks of East Africa, by M. H. **Arsandaux.**—On the lakes of the Upper Engadine, by M. André **Delebecque.** On the relation which exists between the proportion of gluten contained in different wheats and the proportion of total nitrogenous materials, by M. E. **Fleurent.**

DIARY OF SOCIETIES.

THURSDAY, JANUARY 7.

ROYAL INSTITUTION, at 3.—Extinct Animals: Prof. Ray Lankester, F.R.S.

RÖNTGEN SOCIETY, at 8.30.—The Revelations of Radium: Dr. G. B. Batten.

EXPERIMENTAL STUDIES IN DEVELOPMENT.

Einführung in die Experimentelle Entwickelungsgeschichte. By Prof. Otto Maas. Pp. xvi+203. (Wiesbaden: J. F. Bergmann, 1903.) Price 7 marks.

ONE of the most fascinating branches of biological inquiry is that concerned with the investigation of those factors that underlie organisation and determine the course of development of the individual from the egg to its adult condition. From old time the question as to why a hen's egg should give rise to a fowl and not to a lizard or a mammal is one that has invited but never been met with a satisfactory answer, any more than the agencies have been recognised that direct and determine the orderly series of cell divisions culminating in the production of a specific form with all its marvellous organs and complex tissues.

It was formerly believed that, in some mysterious fashion, the actual structure of the adult lay concealed in the egg, much as the flowers of some of our trees can be detected in a resting condition, while it is still winter, by stripping off the bud scales that enfold them. When this view had been shown to be both logically and as a matter of experience untenable, the doctrine of epigenesis displaced it, but this, too, failed to provide a satisfactory basis on which a comprehensive explanation of the phenomena could be built up. Thus in quite recent times a revival of the evolution-theory has arisen, not, indeed, in the older and cruder form, but as promulgated by Weismann and his followers it has appeared to throw light on, and indicate a reason for, the remarkable phases passed through by the cell-nucleus during its division, and at the same time it took cognisance of the extraordinary phenomena that precede and accompany sexual reproduction. It has, however, been subjected to strenuous criticism, and weighed in the balance it, like its predecessors, has been found wanting.

The centre of gravity of current investigation is shifting again from the nucleus to the extra nuclear cell-protoplasm (cytoplasm). As the result of experiment, it has become certain that this part of the cell has to be reckoned with in any theories that pretend to group the facts together, and it is pretty certainly a good deal more than a mere nutritive substance which simply furnishes the nucleus with substances that may enable the latent possibilities of the latter to be converted into actual entities having the specific quality of form and other properties. The old definition of the cell as a mass of protoplasm containing a nucleus is still found to hold good, but the parts played by the two constituents admit of more precise delimitation than was the case even a few years ago.

A step of no small importance was made when it was discovered that by centrifugalising fertilised frogs' eggs, so as to drive the yolk up to one end of the egg, the course of segmentation becomes artificially meroblastic. Thus a condition is produced which is actually met with in many eggs (*e.g.* of molluscs) in which the yolk is present in large quantity and is unequally distributed.

Still more important was the further discovery that the first few blastomeres of a fertilised segmenting egg could be separated and induced to continue their development as isolated individuals. For this afforded an opportunity of deciding whether the organism was the product of its cells, or the cells of the organism. The results strongly point in the latter direction. The same conclusion is reached from the experiments of Hertwig, who by compression succeeded in causing the early cells of the embryo to take up abnormal positions, but the organisation of the larva did not then follow the cell-arrangement, but superseded it. The experiments with isolated blastomeres do not give the same results in all cases. Thus, if they are isolated at the first segmentation of the ovum of an Amphioxus, each gives rise to a small but perfect embryo, and thus behaves as though it were a small egg. In the sea-urchins, the isolated cells at first continue to develop as though the missing part were still present, that is, they give rise to *partial* embryos. But very soon the form of the normal embryo at the corresponding stage is made good, and small but perfect larvæ may result. Yet another example is seen in *Beroë* and some other animals, in which, whilst segmentation at first goes on as though the isolated part were a small egg, at later stages the embryo exhibits various structural defects.

It is very important to notice that these various types of behaviour do not depend on the nuclei. It might be thought that as the small larvæ, at first often defective (sea-urchins), had arisen from cells the nuclei of which had arisen by division from that of the original ovum, the defective character should be correlated directly with this fact. The nuclei might be supposed to have diverged in character, so that, for example, that of one cell contained in itself the latent potentialities of a definite half or other portion of the embryo. But such an explanation is directly contradicted by the facts as shown in Amphioxus, and would not be easily reconciled either with such cases as that of *Beroë* or by the commonly occurring modification of the further processes whereby small, but otherwise perfect, larvæ may arise in spite of the initially different mode of segmentation. Moreover, it has been shown that when freshly fertilised eggs are shaken so as to separate off portions of the cytoplasm *before* segmentation, modifications are produced very similar to those that occur in separated blastomeres. This appears to tell conclusively in favour of the great importance of the cytoplasm as a factor in determining the progress of development. In fact the egg, as has been well said, is itself an organism. Not that the parts characteristic of the adult are there present *in esse*, but the *substance*, the primordial materials out of which the early structures are severally built up, is actually present in the unsegmented egg.

There is some direct evidence available on this point. In many eggs differences of colour or texture can be seen to occupy definite positions in the egg, and if it is rotated these zones often rearrange themselves,

apparently under the influence of gravity, so as to take up the same configuration as before. This fact is highly significant in connection with the production of perfect and normal embryos, although the positions of the earlier formed blastomeres may have been so artificially shifted that their cell descendants occupy abnormal positions in the otherwise normal larva.

The correctness of this general interpretation is also supported by the readiness with which partially separated blastomeres will form double embryos. The two masses of nearly isolated cytoplasm thus develop independently, the lack of adequate contact or continuity between the corresponding parts of the two cells being apparently responsible for the monstrosity. An instructive comparison is afforded by a consideration of the results of artificially induced union of originally separate blastomeres of similar order. If these are approximated so that the axes of the different substances in each are parallel, they segment as one organism, that is, the cell division is coordinated. If, however, the axes are divergent, then each blastomere continues to segment more or less independently, and monsters of various degrees result.

These embryos, arising from isolated blastomeres of the first or following cell-generations, and also those originating from the fusion of previously isolated ones, concur in one remarkable characteristic, viz. the size of the larva at any given stage is proportionate to the relation between the cell from which the embryo actually arose, and the ovum of the species. Thus embryos from either of the first two blastomeres are half the normal size, and so on.

This variation in size is effected by a corresponding reduction in the *number* of cells that go to make up the different parts or regions of the whole, and not by a difference in their *size*. At first sight this circumstance might seem to favour the hypothesis of "unequal" nuclear divisions, *i.e.* the production of daughter cells with constantly segregating potentialities. But any such explanation is at variance both with the facts of development, taken as a whole, and with those of regeneration as well. What the evidence does seem to point to is the existence of definite substances present in the cytoplasm, and that these, though not actually representing the several organs *in parvo*, nevertheless do represent substances necessary to the formation of these organs—a very different thing. It is, then, intelligible why an organism that is left with only half the amount of any one such substance can only produce half the number of cells during cleavage; and a working hypothesis can be formed as to why regeneration is possible in some cases whilst it is apparently excluded in others. There exist strong grounds for believing that the formative stimuli leading to organogenetic development normally reside in the nucleus, but unless the substances capable of responding or of cooperating in the response to a stimulus are present, a normal result need no more be expected than that a printing machine should be capable of turning out a printed page unless the type had been inked.

But though the ground is being broken, much will have to be done before we are in a position to give a satisfactory explanation of the phenomena of development and regeneration. At present it is sufficient to analyse and investigate experimentally the agencies that are concerned in these and other vital processes; we shall thus, and only thus, be able to elevate the surviving elements of existing hypotheses to the rank of well-founded theory.

The volume by Dr. Maas will form a useful source of information for those who may desire to know what is being done in these directions. Its author does not claim to have treated the subject exhaustively, and, indeed, we could wish the sections dealing with the chemical and physical aspects of the matter had been expanded. Nor will the reader who is familiar with the work of Driesch, Roux and others perhaps find much recorded that will be new to him, but the presentation of the subject-matter is, on the whole, judicious and critical. The work covers a wider range than might be gathered from the general tenor of the present article, but as the whole subject deserves more general attention than it receives, it appeared to be more useful to attempt to indicate some of the actual results and the questions arising from them, than merely to give a discursive synopsis of a book that should be read by all who are interested in the more important biological problems of the present day.

J. B. F.

THE ALKALI AND CHLORINE INDUSTRY.

La Grande Industrie Chimique Minerale. By E. Sorel, Ancien Ingénieur des Manufactures de l'État. Pp. 679. (Paris: C. Naud, 1904.) Price 15 francs.

THIS work is concerned with the alkali industry and with those manufactures which naturally group themselves around it. That is to say, it treats of soda and potash, the chief salts of sodium and potassium, the halogens, and the principal industrial compounds of the latter, such as bleaching-powder and the chlorates.

The point of view adopted is essentially that of the manufacturing chemist or chemical engineer. Generally, however, the treatment is rather broader than this might indicate. Thus the history of a process or the growth of an industry is often outlined, and the mode of occurrence of the raw materials used is described more or less fully. As further illustrating the same point we note that, in connection with hydrochloric acid, several pages are devoted to a discussion of the effects which the acid vapours discharged from chemical works produce upon the vegetation of the locality. This, again, is followed by a chapter in which the general principles of the condensation of vapours are discussed from the thermodynamical standpoint. Nor does the author disdain to lighten his pages with occasional items of miscellaneous—not to say trivial—information. We learn, for instance, that in Central Africa "les enfants courent après un morceau de sel, comme les nôtres après un bon-bon."

The salt industry is dealt with in the opening chapter. There is a good description of the production of salt from sea-water, and some particulars of the salt deposits of Cordova, Lorraine, Stassfürt, and Transyl-

vania are included. The treatment of the mother-liquors for the recovery of potassium salts leads then to the next chapter, in which the production of potassium chloride and sulphate is described.

Here in this second chapter we have an instance, graphically told, of the kaleidoscopic changes which an unexpected discovery may sometimes bring upon a seemingly permanent industry. Balard, the discoverer of bromine, had devoted some years of his life to the creation of a new manufacture—the recovery of potassium salts from sea-water, to wit—for the benefit of his beloved Provence. The methods were worked out satisfactorily, an influential company was formed, and everything promised a great commercial success. In fact, the products were already on the market when news came of the discovery, in the "dead lands" round the little Prussian town of Stassfürt, of those great deposits of potassium and magnesium salts which have since made the district famous. Down went the price of potassium chloride to less than one-half its former figure, and with the fall vanished the new French industry. It did not, indeed, succumb without a brave little struggle, and during this the processes were so much improved that, as the author apparently thinks, a fortunate chance might even now bring them to the front again. But at that time, at any rate, the fight was hopeless, and the works round Stassfürt were speedily left victors in the markets which they have ever since controlled.

Potassium carbonate from vegetable sources is next treated of. The burning of plants for the sake of their "potashes" the author regards as a barbarous and brutal kind of industry. It appears that the march of civilisation in the United States is shown by the gradual shifting of the centres where potassium carbonate is prepared—a remark which recalls, though antithetically, the epigram about a nation's progress being measured by the sulphuric acid it requires. It is interesting to note that although at one time potash was largely displaced by soda in manufacturing processes, yet now, thanks to agricultural requirements, the demand for potassium salts is greater than ever.

Iodine and bromine form the subject of chapter iv., and are clearly if somewhat shortly described. The next twelve chapters are occupied chiefly with the soda industry. The ammonia-soda process is lucidly dealt with in two short chapters, and a considerable amount of space is devoted to the Leblanc process. The author justifies this on the ground that the latter method has still some vitality left, and is always capable of making progress. Much of the description is certainly interesting, especially that giving personal details of the discoverer, his successes, and his vicissitudes. But the interest is mainly historical. Even in this country the battle of the ammonia *versus* the Leblanc process can hardly be said to be so doubtful in its issue as the author seems to think it. The electrolytic method is barely mentioned; a little more space might well have been devoted to it.

In any adequate account of the alkali industry this country must figure largely, and such names as those of Gossage, Hargreaves, Mactear, Muspratt, and Mond receive due mention in the present work. The English Alkali Acts, too, although regarded as "Draconian," are nevertheless commended. Indeed, the author is inclined to attribute much of the progress which the alkali manufacture has made in Great Britain to the fact that the makers were forced to collect their hydrochloric acid instead of distributing it broadcast over the countryside. It is, of course, an old story, but it will bear recalling, how, in spite of the great clamour raised, the alkali manufacturers were compelled to take those steps which eventually proved to be their economic salvation. The rejected stone became the headstone of the corner; the troublesome by-product presently supported the whole industry.

Chlorine, bleaching-powder, and chlorates are dealt with in the last five chapters. There is nothing particularly new, but the descriptions include the standard processes, such as those of Deacon, Weldon, Dunlop, Mond, and Péchiney, and give a good general idea of this branch of chemical industry.

The work contains a number of illustrations, but lacks an index. It will be useful to those who require something more complete than a general text-book description, but less extensive than Lunge's standard treatise.

C. Simmonds.

THE ELEMENTS OF ELECTRICAL ENGINEERING.

Electricity and Magnetism. By C. E. Ashford, M.A. (London: Edward Arnold, n.d.) Price 3*s.* 6*d.*

Electric and Magnetic Circuits. By Ellis H. Crapper, M.I.E.E. (London: Edward Arnold, n.d.) Price 10*s.* 6*d.*

A Text-book of Electrical Machinery. Vol. i. Electric, Magnetic and Electrostatic Circuits. By H. J. Ryan, H. H. Norris, and G. L. Hoxie. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1903.) Price 2.50 dollars.

THE best method of training electrical engineers will probably remain a subject of discussion so long as the profession continues to be a profitable one. Whether recourse should be had to the factory or to the technical college; whether a combination of these two is desirable or necessary, and if so, in what manner they should be combined; and whether the course at the technical college should be entirely by lecture and experiment, or should make free use of that royal road to excellence, the text-book; these and kindred questions will always be discussed and will never be settled. Whilst the discussion goes on the writers of text-books continue to flourish until the difficulty of deciding whether to have recourse to text-books or not is overshadowed by the greater difficulty of deciding which would be the most profitable to read. The three books before us illustrate how the budding electrical engineer may be caught when he is yet fresh in knickerbockers and led by easy steps to a complete mastery of his profession. Mr. Ashford's "Electricity and Magnetism" is a school-book; it starts by assuming that the pupil has no knowledge of the subject at all, and, leading him by a path of experimental inquiry, ends by leaving him well fitted to begin on Mr. Crapper's more advanced treatise. This read,

and the fundamental principles of continuous current circuits mastered, it only remains to study alternating currents in the work of Messrs. Ryan, Norris and Hoxie.

It is difficult to find anything particular to say of either of the three books, since each treats its subject in the manner which has become by now fairly familiar. They all possess certain merits not to be found in other books of a like kind, and certain defects which it is easy enough for the critic, who has only to read and not to write the book, to make much of. For example, Mr. Ashford proves Ohm's law with electromagnetic instruments, a logical mistake which it seems hopeless to eradicate from the text-book; Mr. Crapper does not prove it at all, but states that "on account of its importance as the fundamental law of electrical measurements, it may be considered in the strictest sense a law of nature," which seems to us rather a novel criterion for laws of nature. Mr. Crapper is also somewhat loose in his use of the terms force, energy, and power ("watts of energy," for example, is an expression rather difficult to understand), and, indeed, in his definitions generally —an electrolyte is defined in one place as "a compound liquid with a metallic salt in solution." These are, perhaps, slight defects, but one is justified in requiring more exactness of expression and more careful attention to detail in a text-book than one would think necessary in a lecture. The best justification that a text-book can claim is that it gives precision to the knowledge obtained experimentally in the laboratory.

Mr. Ashford's book is intended as a laboratory handbook; in our own opinion the last thing wanted in a laboratory is a handbook. Such things are never to be found for the practical experiments the electrical engineer has to make when his days of school and college are over, and the greatest benefit of the laboratory training is that it should train the student to walk alone. When experiments are so carefully described, and the results to be got and the conclusions to be drawn from them so plainly pointed out as in this book, the value of the experiment is greatly discounted, if the student even takes the trouble to carry it out properly. Mr. Crapper, on the other hand, errs by giving too much importance to the exercise class; if any student works through the enormous number of examples given in the book he will have done a great deal of arithmetic, but we doubt whether his engineering faculties will have benefited much.

Messrs. Ryan, Norris and Hoxie proceed on what is, at any rate to English readers, the somewhat novel plan of plunging forthwith into the phenomena of alternating currents, "from which the treatment of continuous current phenomena follows naturally." This seems to us rather putting the cart before the horse, as we should certainly think the understanding of alternating currents must follow, and even then with difficulty, that of continuous current phenomena. This method involves also considerable mathematical knowledge in the student, and from this point of view alone seems scarcely the most suitable to adopt.

In conclusion, we may repeat that fault-finding is easy, and that these three books have much to recommend them. They are thoroughly up-to-date, and will compare very favourably with any three other books covering the same ground which we can call to mind. Their fault is not that they are bad text-books, but that they are good text-books.

MAURICE SOLOMON.

THE PHYSIOLOGY OF MENTAL ACTIVITY.

Etudes de Psychologie physiologique et pathologique. By E. Gley. Pp. viii + 335. (Paris: Félix Alcan, 1903.) Price 5 francs.

TWO-THIRDS of Prof. Gley's book are devoted to a historical and critical review of our knowledge of the physiological changes that accompany intellectual activity. The writer gives a lucid account of his own contributions to the subject in chapters upon the relation of mental work to the cardiac, respiratory, vascular, excretory, and thermogenic mechanisms. He concludes that mental work is accompanied by increased rate of heart-beat (at least in the early stages of activity), by arterial constriction and increased peripheral resistance in the extra-cerebral circulation, and by active dilatation of the arterioles of the brain. No mention is made of the experiments and views of British physiologists in regard to the much-debated presence of a vaso-motor mechanism in the brain. The author bases his affirmative conclusion merely on a study of the changes in form of the carotid pulse-curve during intellectual rest and activity. He is also inclined to believe that during intellectual activity the temperature of the brain rises slightly. Yet the evidence in favour of this view seems very far from adequate, for it has never been shown that the amount of carbonic acid evolved is increased during the activity of nervous tissue, and we are powerless to decide whether the slight rise of cerebral temperature may not be due to other causes, *e.g.* to the increased blood supply to the brain, to diminution in loss of heat from the skin arising from the already mentioned peripheral vascular constriction. To cerebral metabolism the author also attributes the increase of calcium salts in the urine during intellectual activity. This increase is said to be accompanied by more abundant excretion of urine and of magnesium salts and phosphoric acid.

Throughout the book Prof. Gley does not attempt to veil his intention to find analogies between cerebral and glandular activity, but *a priori* views, however excellent, are of little real avail in the solution of such an unusually difficult problem. There is, indeed, one complicating factor which is invariably neglected by physiologists, to which attention may be directed here. It is now generally believed that no mental process is possible without the simultaneous production of efferent impulses—in other words, thoughts must express themselves in muscular activity. Even if this maxim exaggerates the truth, there can be no doubt that, as a rule, active intellectual efforts pass over into, and to some extent manifest themselves as, muscular contractions. These contractions may appear as vaso-motor changes or as involuntary movements, and they are largely responsible, at least when

well pronounced, for changes in the general feeling or emotional tone of the individual. Now, in the first place, it is impossible to rule out changes in emotional tone altogether during any period of intellectual activity. Emotional tone is always present and always changing, obviously so where, as in several of Prof. Gley's experiments, the intellectual work consisted in reading. Secondly, even if we could maintain a constant state of feeling, we should still be ignorant how far changes in the blood-circulation accompanying purely (!) intellectual activity are due to the aforesaid tendency of ideas to realise themselves in motor activity, and how far to physiological conditions essential for the manifestation of that intellectual activity.

The three remaining chapters of this interesting book are concerned with unconscious muscular movements, the muscular sense, and abnormalities in the sexual impulse. Embodying as they do material already published by the author some eighteen years ago, they hardly call for analysis here.

C. S. M.

OUR BOOK SHELF.

L'Éducation fondée sur la Science. By C.-A. Laisant. Preface by Alfred Naquet. Pp. xlv+153. (Paris: Félix Alcan, 1904.) Price 2.50 francs.

There is a special interest attaching to this book since it shows convincingly that those reforms which are being urged with such conspicuous success in this country are also engaging the attention, and calling forth the proselytising zeal, of French men of science. M. Laisant does not seem to have acquainted himself with the progress of English reform in mathematical teaching. Had he studied the reports of the committees of the British Association and the Mathematical Association, and had he realised the widespread alteration in the mathematical syllabuses of our public examinations, he could not have written :—" l'éducation anglaise, par exemple, est sur certains points (et surtout en ce qui concerne la géométrie), plus pitoyable encore que la nôtre, et elle semble avoir beaucoup plus pour objet de déformer l'esprit que de développer l'intelligence, lorsqu'elle impose la récitation par cœur du texte d'Euclide" (p. 73). The suggestions made in M. Laisant's discourse " L'Initiation Mathématique " for the improvement of mathematical teaching in French schools are not only familiar to our teachers, but are, we are glad to know, widely used by them.

Similarly, if we judge from the address " L'Initiation à l'Étude des Sciences physiques," it is clear that the necessity for the employment of experimental methods in the teaching of physics and chemistry is much more widely recognised with us than in France. One may go even farther and say that our practice is in advance of the ideal which M. Laisant places before his readers. We have learnt that the only really satisfactory way for a student to learn science is himself to enter upon simple experimental research work, and by his own efforts to demonstrate the truth of chemical and physical generalisations; M. Laisant seems to imply that experimental demonstration by the teacher may suffice.

It is possible here to refer only to a few of the interesting questions raised in the other two lectures—" Éducation scientifique et Psychologie" and " Le Problème de l'Éducation." We are heartily in agreement with M. Laisant that " il est certain que les classes peu nombreuses sont une des conditions premières et essentielles d'une éducation raisonnable" (p. 97), but since this means more teachers and a correspondingly larger national expenditure, we must wait in both countries for a greater belief in education on the part of the authorities. M. Laisant considers that " l'enfant est un être raisonnable; et le but le plus essentiel de l'éducation" is " de développer en lui la faculté du raisonnement" (p. 66). This is, however, not the general experience, and Spencer's is probably the wiser view that " only after an ample fund of observations has been accumulated, should reasoning begin."

The author's remarks on the teaching of morality and religion in schools will commend themselves to most men of science, who will agree that " l'éducateur habile, en stimulant dans l'esprit de son élève le culte de la vérité, en tirant parti de tous les exemples, de toutes les observations, de l'expérience quotidienne, arrivera sans peine à façonner graduellement cette conscience d'enfant pour en faire une conscience humaine" (p. 120).

A. T. S.

The Museums' Journal. Vol. ii. July, 1902, to June, 1903. (London: Dulau and Co.)

With the commencement of the present volume this important publication entered on a new phase of its existence, appearing in monthly parts instead of solely as an annual report. Although this change is undoubtedly for the better, it renders much of the contents of the complete volume rather ancient news, and some of the articles in the one before us have already received mention in our columns.

As regards the general condition of the Museums Association, it is satisfactory to learn that during the period covered by this report there has been a considerable increase of membership, both on the part of museums and of associates, and that this increase in the finances has been further augmented owing to the circumstance that several museums previously on the list have agreed to double their subscriptions in order to aid in defraying the increased expenditure inseparable from the monthly publication of the *Journal*.

As in the case of its predecessor, the contents of this volume cover a very wide field indeed, embracing everything connected with museums and natural history and art exhibitions, including their publications. A highly satisfactory feature is the amount of attention directed to rendering museums as interesting and instructive as possible to the general public, by whom they are maintained, and whose benefit should undoubtedly be their first aim and object. In connection with this subject we may especially refer to the article on the Haslemere Educational Museum, by Mr. E. W. Swanton, which, to judge from the appended plan, appears to be admirably designed and arranged for its purpose. In addition to general and local collections, this institution includes the almost unique feature of an aviary and a vivarium.

Whatever may be the case in this country, in America, as we learn from an article by Mr. F. C. Baker, the introduction of numerous well written descriptive labels in museums has proved a decided success. " Visitors," he writes, " have been seen to spend but a few moments examining cases installed by the old method, while a case containing some interesting material . . . will be pored over for several hours, which fact conclusively proves that the addition of carefully prepared descriptive labels is absolutely essential to the success and usefulness of a museum."

Labels in museums also form the subject of an article by Mr. F. A. Bather, who discusses certain difficulties in connection with the application of

vernacular names to specimens. Special reference is made to the case of the American bison, the author stating that no European naturalist could be prevailed upon to apply to that animal its Transatlantic title "buffalo." If, however, he will visit the mammalian gallery of the museum to which he himself belongs, he will find the label "Buffalo, in America" attached to the stand of one of the specimens of that species.

Lack of space alone precludes further reference to the contents of a volume which cannot fail to be of great value to all who have to do with museum arrangement. R. L.

Laboratory Physics. By Dayton Clarence Miller, D.Sc. Pp. xv+403; diagrams. (Boston, U.S.A., and London: Ginn and Co., 1903.) Price 8s. 6d.

THIS manual by the professor of physics in the Case School of Applied Science, Boston, is the result of twelve years of teaching experience, and most of the descriptions have been employed in type-written form for the past six years. It is not intended as a preparatory course; at the same time the majority of the experiments are of a fairly simple type. Constant references to existing text-books of practical physics (both English and American) show that the author has made free use of all sources of information, which is duly acknowledged. Many of the experiments are not usually met with in text-books, or at any rate are not met with in so full a form. Thus the complete calibration of a scale by Neumann and Thiesen's method is fully described (though without the theory, for which reference is made to Guillaume, "Thermométrie"), and there is an account of the use of Michelson's interferometer.

The author's aims are admirable. "A Laboratory course is not considered as consisting of a certain number of exercises to be worked out by each student, and to be complete when these are finished, but rather as consisting of a definite amount of time spent in judicious experimenting."

The descriptions of experimental details are good and are not overdone. The student will not be tempted to perform merely parrot work. He will require to think and scheme in many ways before his apparatus will prove tractable, and is not this just as it should be? We wish we could say that the days of organ-grinding were past.

No attempt is made to give even an outline of the *theory* of the experiments, and as the references are almost entirely to practical text-books, the student will require guidance in his choice of books from which the theory may be obtained. The manual would be improved if references to theoretic text-books were given as well.

The book is excellently printed and illustrated, and is very free from errors of all kinds. We notice only an erroneous definition of viscosity (p. 117), and the statement on p. 390 that $\pi/4 = 0.079577$, whereas this number is the value of the reciprocal of 4π.

Opere di Galileo Ferraris. Vol. ii. Pp. vi+473. (Milan: Ulrico Hoepli, 1903.)

THE memoirs included in the present volume may well be regarded as classical in the annals of applied electricity, since they belong to a period which has witnessed the birth and growth of the applications of electrical energy to lighting and power transmission. The first paper is an illustrated account, published in 1876, of the then "new induction machines," which, as the figures show, differed only in points of detail from the dynamo of the present day. This paper is followed by a series of five lectures on electric lighting, delivered in the spring of 1879, just about the time when, for the first time, the Piazza Colonna at Rome was brilliantly illumined by "Jablochkoff candles." The next 153 pages are occupied with a report by Prof. Ferraris on the industrial applications of the electric current, at the Paris Exhibition of 1881. In connection with that exhibition, we next have reports of the commissions appointed to deal with the determination of the ohm, atmospheric and terrestrial electricity, and the choice of photometric units. The subsequent contents comprise Prof. Ferraris's award of the prize offered in 1884 by the municipal government of Turin, reports on the Paris Exhibition of 1889 and the Chicago Congress of 1893, a discourse delivered before the Lincei Academy in 1894 on electrical transmission of energy, and an obituary notice of Gaulard, to whom as discoverer of the transformer Prof. Ferraris gives the highest praise.

Elements of the Theory of Integers. By Joseph Bowden, Ph.D. Pp. x + 258. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1903.) Price 5s. net.

JUST as the names of plants and animals are constantly being altered, so the ranges of mathematical study included under such general titles as "Algebra up to the Binomial" or "Trigonometry up to Solution of Triangles" are changing as time goes on. In the "eighties," the average tripos candidate would understand by "elements of the theory of integers" the chapter in Todhunter's "Algebra" which taught him to "state and prove Fermat's theorem." The present book deals with nothing of this kind, but is devoted to proving such rules of algebra as that if $a > b$ then $b < a$, or $(-a)\times(-b) = +ab$. In the course of this work a number of cabalistic signs are introduced with which most mathematicians in this country are unfamiliar. Whether these symbols are necessary or even helpful must remain a matter of opinion, but there is no excuse for the author's incorrect spelling of the English language, as exemplified by "we hav," "ther ar," "therfor," "positiv," "canceld," "fixd," "giv."

Géographie Générale. By M. G. Lespagnol. Pp. vii+460. (Paris: Ch. Delagrave, 1903.)

THIS is an unusually comprehensive course, not of general geography as we know it in this country, but of physical geography, to which has been added a short history of geographical discovery and an essay on the growth of geographical science. The physical geography part of the volume follows the historical portions, and constitutes about three-quarters of the volume. A great deal of geological information is placed before the reader, much more than is commonly included in English books on physiography. The illustrations are numerous and generally good. There are many useful tables, and the book, as a whole, is a good introduction to an important subject. The absence of an index and a table of contents will be much regretted by students.

Pushing to the Front, or Success under Difficulties. By Orison Swett Marden. Pp. viii+416. (London: Gay and Bird, n.d.) Price 3s. 6d.

THE author's object in writing this book was "to encourage, inspire, and stimulate boys and girls who long to be somebody and do something in the world, but feel that they have no chance in life." Among the unusually large number of examples of distinguished men who have overcome successfully all sorts of difficulties, many great men of science are included, and Agassiz, Dalton, Darwin, Davy, Faraday, Franklin, Galileo, Humboldt, Huxley, and Hugh Miller may be mentioned. The book should certainly provide young men with an incentive to an increased effort to make the fullest use of their faculties and opportunities.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Radio-active Gas in Mineral Springs.

IN a letter to NATURE of August 13, 1903, it was announced that experiments carried out at the Blythswood Laboratory had shown the presence of a radio-active constituent in the gases derived from the mineral waters of Bath. An account of our further investigations has been given in a paper read before the Royal Philosophical Society of Glasgow, November 18, 1903. Samples of water from the Buxton springs have been tested with results exactly similar in character to those given by Bath waters. In both cases the ionisation-current through the gas obtained from the water increased to a maximum in about one hour from the commencement of an experiment, and then diminished to the normal value. In a note added to this paper, December 15, 1903, an experiment is described similar to one carried out by Mr. E. P. Adams (*Phil. Mag.*, vol. vi. p. 563, 1903). A current of air was drawn through a very dilute solution of a radium salt, and then through a Winchester quart containing distilled water. The air current was continued for two hours. The distilled water after this treatment was tested in exactly the same manner as the Bath water, "the results being in all respects similar. . . . It is therefore probable that the radio-activity of these (mineral) waters is due to the presence of radium near their source."

This anticipation has been confirmed by the Hon. R. J. Strutt's discovery of radium in the iron deposits left by the hot springs of Bath.

We have recently obtained conclusive evidence of the presence of radium emanation in the Buxton springs through the kindness of Mr. J. W. Wardley, who has collected samples of the gases that rise through the water and forwarded them to us for examination. In our former experiments with water sent from the springs the amount of gas obtained was extremely small, and the consequent activity inconsiderable. We now find that the activity of the gas falls to half value in about three and a half days, the corresponding time for the radium emanation being 3·71 days (Rutherford).

It would be interesting to know whether treatment by the gases obtained from the springs possesses any therapeutic value.

BLYTHSWOOD.
H. S. ALLEN.

Blythswood Laboratory, Renfrew.

Projection of Imitation Spinthariscope Appearance.

IN thinking over how to exhibit to an audience the appearance of a zinc-sulphide screen bombarded by radium, one of my sons suggested that a kinematograph film often imitated the effect, by reason of its punctures being thrown on the screen by intermittent light. Accordingly he made a model with two numerously punctured plates mounted on eccentrics so as to slide over one another in a periodic fashion. It is sufficient, however, to hold two punctured plates by hand in the place of a lantern slide, and move them irregularly over each other slowly.

OLIVER LODGE.

American Tropical Laboratory.

THE Director of Kew presents his compliments to the Editor of NATURE and requests the publication of the enclosed letter.

Kew, January 8.

New York Botanical Garden,
Bronx Park, New York City,
December 26, 1903.

My dear Sir William,

Referring to my letter of August 14, 1903, I take pleasure in stating that the group of buildings of the Colonial Government of Jamaica at the Cinchona Botanical Garden will be maintained as a botanical laboratory by the New York Botanical Garden under an agreement with the Colonial Government, and with the cooperation of the Department of Public Gardens and Plantations of Jamaica; sufficient land for experimental purposes and for a nursery is included in the leasehold privileges. The buildings include a residence known as Bellevue House, three laboratories, two ranges of glass, and one or two small buildings suitable for lodgings.

Investigators are offered the following facilities:—

(1) The use of tables in the laboratory buildings.

(2) Lodging in Bellevue House or in one of the other buildings at Cinchona.

(3) The use of land for experimental purposes.

(4) Privileges to study the plantations at Cinchona, and also those at Hope and Castleton Gardens.

(5) Privilege to consult the botanical library of the Department of Public Gardens and Plantations at Hope Gardens, and to take books therefrom to Cinchona under such conditions as may be imposed by the Director of Public Gardens and Plantations.

(6) An immense number of indigenous species are within easy reach in the primitive forests adjacent to Cinchona.

All persons who may apply for permission to study at Cinchona must submit such evidence as the Director-in-Chief of the New York Botanical Garden may require that they are competent to pursue investigation to advantage. While in residence at Cinchona they will be under the supervision of the Hon. William Fawcett, Director of Public Gardens and Plantations, to whose interest and advice the establishment of this American tropical laboratory is largely due.

A laboratory fee, payable to the New York Botanical Garden, will be required of persons granted the above privileges.

Upon approval by the scientific directors of the New York Botanical Garden, any other institution, society or individual may be assigned the use of a table at Cinchona by the payment of one hundred dollars annually, which will entitle them to nominate students desiring to avail themselves of the facilities of the laboratory for admission without the payment of fees, but not more than one person may be granted the use of any table at the same time.

The necessary expenses for a month's residence at Cinchona, including travelling expenses to and from ports on the Atlantic seaboard of the United States, are from 140 dollars to 200 dollars; for two months' residence 160 dollars to 230 dollars.

Dr. MacDougal will be glad to give you any further information concerning this subject that you may care for, and we hope that you or some of your students may be able to utilise the resources of the laboratory from time to time.

Yours sincerely,
(Signed) N. L. BRITTON,
Director-in-Chief.

Escape of Gases from Atmospheres.

IN the Literary Supplement of the *Times* of December 25, 1903, an erroneous statement is on p. 375 placed before its readers, to the effect that our alleged knowledge of the escape of some gases from the atmospheres of planets and satellites is based on an assumed absence of helium from the earth's atmosphere, and has been disposed of by the discovery that helium is present. A brief letter was addressed to the editor of the *Times* giving proofs that the above statement is incorrect, and from this letter an extract has been published as a note in the next number of the Literary Supplement. The matter concerns one of the great cosmical agencies of nature, and I therefore request you to allow me to deal with the subject in the more adequate way which is permissible when addressing a scientific journal.

The problem of the escape of gases from atmospheres has been approached in two ways, both of which the present writer has tried, and one of them has also of recent years been attempted by other scientific men:—(1) The problem has been treated deductively by ascertaining the law of the distribution of speeds among the particles of a hypothetical kinetic system, so constructed as to be a model of gas simple enough for human mathematics to enable us to compute the distribution of speeds within it, and which it was hoped

would sufficiently represent what goes on in the actual gases with which we have to deal. This expectation, unfortunately, has not yet been fulfilled (see *Proceedings* of the American Philosophical Society, vol. xlii. p. 108). (2) The problem has been treated inductively by arguing upwards from known facts of nature. It is in reference to this second method that the *Times* makes its statement.

So far from its being true, as was supposed by the *Times*, that the argument is based on the assumption that there is no helium in our atmosphere, it is pointed out in the first memoir upon the subject that there must be just such traces of helium and hydrogen in our atmosphere as have since been detected (see *Scientific Transactions* of the Royal Dublin Society, vol. vi. pp. 308 and 309).

The facts of nature which were made the data of the investigation are four in number. The first of these is *that there is either no atmosphere or very little on the moon*, from which it is inferred that the atmosphere which the moon shared with the earth when the two bodies separated, and whatever atmospheric gases have since been evolved upon the moon, have by this time escaped. It can be shown that if this be so, then hydrogen, if uncombined, must be able to escape from the earth. There is, however, but little *free* hydrogen upon the earth, and in the atmosphere there is only the merest trace. If there is in this trace any excess over what returns to the earth in rain or in other ways, this excess is on its way upwards towards the penultimate stratum of the atmosphere, which is the part of the atmosphere from which gases escape. Accordingly, the amount of hydrogen which succeeds in getting away from the earth must be very small, while the store of hydrogen locked up in the ocean and in the solid earth is enormous. It can, moreover, be shown that there is a minute accession of hydrogen to the earth from outside, so that on the whole the quantity of hydrogen upon the earth may be almost stationary.

The second and third facts used as data are that helium and free hydrogen are being continuously supplied from the earth to its atmosphere, and that—probably in both cases, certainly in the case of helium—only a very small percentage of the gross supply is being washed down by rain or in other ways returned to the earth, notwithstanding which *neither the hydrogen nor the helium has gone on accumulating in the atmosphere*. From this it is inferred that the quantity which is present in the atmosphere has adjusted itself to be such that the outflow of these gases from the upper regions of the atmosphere balances the net supply which the atmosphere receives from below.

One other fact in nature is used as a datum that the earth's potential of gravitation is sufficient to prevent any sensible escape of the lightest of the *abundant* constituents of its atmosphere. This lightest abundant constituent is the vapour of water.

A further paper has been published which is devoted specially to dealing with the behaviour of helium in the earth's atmosphere (see *Astrophysical Journal*, vol. xi. p. 369). In this paper it is shown from the marvellously accurate determinations made by Sir William Ramsay and his assistants that the supply of helium to the atmosphere by hot springs, and presumably the helium which oozes up elsewhere through the soil, is from 3000 to 6000 times more than can be accounted for as being a return to the atmosphere of helium which had been washed down by rain; whereas the argon, oxygen and nitrogen in such springs are all of them present in proportions which are consistent with their having been carried down by rain from the atmosphere. From which it is inferred (1) that nearly the whole of the small quantity of helium in the atmosphere is on its way outwards; (2) that helium would have become a larger constituent of the atmosphere by reason of the influx from below if there had been no simultaneous outflow from above; (3) that the rate of this outflow is presumably equal to the net rate of supply.

The escape of helium from a member of the solar system must be facilitated by the circumstances that those radiations from the sun that can affect helium have the full strength of radiation from the photosphere, inasmuch as the helium in the sun's outer atmosphere emits radiations of the same intensity as the photosphere. This is evidenced by the great helium line D_3 being as bright as the neighbouring part of the spectrum of the photosphere. We have, moreover, to take into account that outpour of corpuscles from the sun which, in the upper regions of our atmosphere, is able to excite into intense activity the internal motions of krypton which produce the green auroral line, and presumably with equal and perhaps increased vigour imparts energy to the molecules of helium which range to still greater altitudes.

G. JOHNSTONE STONEY.

30 Ledbury Road, W., January 7.

On the Origin of Spiral Nebulas.

THE ever increasing interest and importance of studies relating to celestial phenomena naturally lead up to questions which, in the present state of our knowledge, can (from the purely theoretical standpoint) in some cases be answered in a fairly satisfactory way.

The object of this note is to present certain views (some of which are believed to be new) on the probable origin of spiral nebulas, having given to start with an incandescent body like our sun.

From theory and observation we know that when different parts of the same fluid body have largely different temperatures the mass is in unstable equilibrium. The constant tendency of the resulting flow of the fluid is to equalise the temperature throughout the mass.

If the maximum temperature is in the interior of the body and the outside is exposed to a much lower temperature, the flow near the surface, through a gradual congealing of the latter, will be retarded. Such a surface will then also act as an insulator and shield to prevent both the too rapid loss of internal heat and the free escape of the accompanying gases.

The visible photosphere of the sun is known to be in a highly heated condition, and the fact that it is almost constantly being ruptured (in some zones more strongly and frequently than in others) shows—reasoning from analogy—that the solar surface has the properties of a fluid in such a state of unstable equilibrium that the superheated confined masses in the interior are still able to break through this surface at many points.

If the sun did not rotate on an axis, this surface would probably be of uniform strength throughout, for the interior circulation would then be radial. The resultant, however, of the rotary and radial forces acting on each particle produces not only an ellipsoidal figure, but also has the tendency to cause each ascending particle to move towards the equator.

As a result there is a tendency to produce surface-flow towards the equator causing an accumulation of cooled matter along the zone which but for this flow would be the weakest part of the whole rotating surface. It is therefore to be expected that two zones of least strength should exist in the solar surface, symmetrically situated with reference to the equator, but at some distance from it.

Now what is most likely to happen after a body like the sun has contracted to such a radius that the surface exists in the plastic or semi-solid state?

Such a surface will act as an insulator producing a more nearly uniform internal temperature and a consequent decrease in the interior circulation. The surface flow having ceased, and the axial velocity of rotation having increased, the zone of least surface-strength will coincide with the equator.

During the time required to reach this stage of the body's history it is probable that the lesser vents were gradually closed as the surface became stronger, resulting in periodic outbursts of increasing magnitude at a smaller number of openings until finally these also were closed.

As the *weight* of each particle of matter in the surface has increased inversely as the square of the radius (the sun's radius being unity), the internal pressure has been increased. Through the continued contraction of the outer surface this pressure, no longer relieved by periodic outbursts, increases far beyond the limit necessary to support the surface; as a result, the outer boundary grows hotter and consequently weaker, so that at last a great rupture of the surface takes place on or near the equator.

The moment this break occurs, the interior masses and

gases, which under great pressure have the properties of a fluid, move with various velocities, and along more or less curved lines toward the opening.

That component of the resulting momentum which acts at right angles to a diameter through the point of rupture causes an excess of pressure along this diameter; this excess, in the nature of a reaction, acting on a surface already strained to near the breaking point, finally causes a second rupture at the diametrically opposite part of the body.

The ejected masses will not all have the same velocity; those parts near the outer boundary of each stream will be deviated and retarded through side currents and friction at the aperture; the central parts of the stream will, in general, acquire the highest velocity, sufficient to carry the lighter matter in a radial direction far beyond the sphere of sensible attraction of the parent mass, where it finally attains a uniform velocity. The heavier masses and those near the borders of the opening will form secondary streams having various inclinations and velocities which, if there were no rotation, would be incomplete arcs of hyperbolas, parabolas and ellipses, in all of which the lighter masses would continually be outstripping the heavier ones.

Through the rotation, however, the outer parts of every stream are left behind the parts nearer the origin, so that each stream falls into a spiral curve of a more or less complicated form, resulting in an increase in the confusion of detail with diminishing distance from the centre.

If the orifices are on the equator, the radially ejected streams will be plain spirals. If the line joining the two orifices is inclined to the equator the streams will be of double curvature, each producing a spiral in the form of a helix[1] (conical). This class of nebulas not being confined to a single plane will, as a rule, exhibit much confusion of detail in projection.

In general a practically straight line drawn from the origin to any part of the plane spiral represents the actual path traversed by the matter in that particular part of the spiral, and the angular length of any given mass, measured in the direction of increasing distance from the origin, represents the corresponding arc through which the parent body rotated, in the opposite direction, while this particular mass was being cast out.

The two principal factors which operate to produce the observed form of any particular spiral are:—(1) internal pressure; (2) velocity of axial rotation.

The decrease in pressure, after the surface has been ruptured, may in some cases be so rapid that the orifices close up before the body has completed a single rotation; such a body will, later on, repeat the process, the orifices remaining open for a longer period; later still the surface will have reached such a condition that the orifices remain open for an indefinite period, finally reaching a stage represented (on a small scale) by the earth's present condition.[2]

If the earlier conditions were such that at the time of the first great eruption long ages were required for a single rotation of the body, the observed form indicates that the internal pressure remained nearly constant, and that the angular velocity was continually being accelerated. (Owing to the removal of heated matter from the interior the contraction was much more rapid than that which would have resulted from simple loss of heat at the surface.)

According to this theory, then, the spiral nebulas reveal to us the past history of the forces operating at the mouths of the two opposing volcanoes.[3] The fluctuations in the forces and in the relative amount of matter belched forth simultaneously by each crater are faithfully recorded in the often twisted, broken, serrated and irregular aspect of the masses which make up the general outline of the main hyperbolic spiral curves. This history covers the period from the first great catastrophe, represented by a distant large mass at the extreme outer limit of one branch, telling us which of the two orifices was the first to relieve the internal pressure, down to the time when the outer portions of the numerous inner streams having less initial velocity but the same angular length—or perhaps the outer portions of the main streams of a later eruption—reached to such distances from the centre as to produce too much confusion of detail for further trustworthy analysis of the form seen in projection.[1]

The generally more dense and more luminous inner boundary of the main spiral curves plainly indicates that after all these ages the lighter more swiftly moving but later ejected particles are still bombarding the earlier slower moving masses. Every time either orifice came nearly in line with, say, a particular distant previously ejected mass, the more swiftly moving particles were sent on their invisible course, many on the way transferring part of their energy of motion to other particles and to the production of the accompanying phenomena of heat and light; others to find free passage, leaving far behind those masses ejected in the same direction at previous rotations (thus crossing in radial directions the space between the main spiral arcs), finally to overtake, some to bombard the particular mass, thus helping to keep it luminous, others, like all parts of the main spiral, to continue their outward journey indefinitely, or until some other obstruction changes their energy of mass-motion into a different equivalent. Through the action of gravity the particles ejected by one body—aided by those coming from other sources—play their part to re-create the conditions leading to a repetition of the parental experiences.[2]

Isolated or heavier condensations on the spiral arcs will generally take on a cometary form indicating the direction from which the particles come. I would suggest that a long nebulous mass, as, for instance, H.V. 14 Cygni, may be a part of some great spiral (perhaps approaching and relatively near to the earth); if this is so, the general direction of the parent mass is plainly indicated in the visible structure of this nebula.

When the eruptions are periodic and of very short duration, the heavy surface-matter ejected at each re-opening of the craters will not be carried beyond the limits of the system. Certain results I have recently obtained seem to show that the masses forming star-clusters are the innermost parts of spiral structures similar to those considered in the present paper.

In the case of the great cluster in Hercules, the star-like masses are found to be connected by *nebulous streams which first leave then return towards the centre of the cluster*, showing that the initial velocity of ejection was insufficient to carry these masses (which can hardly be called stars in the ordinary meaning of the word) beyond the sphere of central attraction. A similar arrangement is found to exist among the stars near γ Cassiopeiæ. The two known nebulas near this star (first photographed by Barnard and Wolff) are but the more condensed parts of a broad spiral-like nebulous band (made up of similar condensations) which can be traced from near the middle of the second quadrant up to within a few minutes of arc of the naked eye star in the fourth quadrant. More complete details have been sent to the *Astronomical Journal* for publication.

In conclusion, it may be permitted once more to direct attention to a unique case in solar observation, bearing, as it does, directly upon the subject of the origin of spiral nebulas. How much, or rather how little, importance has been attached to this particular phenomenon, and to the "mechanical theory of comets"[3] put forward at the time,

[1] Photographs of these objects can be found in various astronomical publications. The most complete work in this line has been done by Isaac Roberts, D.Sc., F.R.S. See his "Photographs of Stars, Star Clusters and Nebulæ," vols. i. and ii.

[2] It is worthy of notice, in this connection, that the two most disturbed terrestrial regions are diametrically opposite to each other and near the equator. The deep-seated character of these disturbances is shown quite conclusively by the observed phenomena. Martinique belongs to one region, Krakatoa to the other.

[3] Spectroscopic and photometric changes in the light of certain fixed stars, when considered in connection with the phenomena which would be produced by two radially moving columns of matter (incandescent at the orifices and rotating about a fixed axis inclined at a given angle to the line of sight), might in some cases lead to more satisfactory explanations of the observed data.

[1] Through irregular variations in the pressure at the orifices, and through differences in the amount of matter ejected at different times, an endless variety of forms can be produced.

[2] Readers acquainted with Lockyer's views will notice that I adopt the theory of the meteoric constitution of nebulous matter. The evidences in favour of this theory are fully set forth in the work entitled "The Meteoritic Hypothesis," by Sir Norman Lockyer, K.C.B., F.R.S.

[3] See "Contributions from the Lick Observatory," No. 4, p. 118 *et seq.* This theory calls for just such crucial, seemingly abnormal but really typical phenomena as were presented by Borrelly's last comet.

is voiced in the language of one of the ablest descriptive writers on astronomical subjects of the present day. On p. 127 of her late admirable work entitled "Problems in Astrophysics," Miss Clerke dismisses the subject with the words, "*The only genuine 'eclipse comet' so far captured was that seen and photographed at Sohag 17th May, 1882.*" This talented writer makes not the slightest reference to the fact that the 1893 phenomenon differed in one important particular from all those it is said to resemble—that it possessed the one *observed* element which even the genuine object does not lay claim to, namely, the photographs prove that this object *moved*, receded from the sun through an angular distance equal to two-thirds of the solar diameter in less than four hours.[1] On the Mina Broncis photographs this object is plainly connected with the sun by a single, straight, isolated coronal stream.[2] J. M. SCHAEFERLE.

Ann Arbor, December 10, 1903.

Dynamical and Granular Media.

I SHOULD be very much obliged if any reader of NATURE who has studied the matter could enlighten me on the following point.

We may regard a *dynamical system* as commonly understood as being a system which, when left to itself, obeys the Hamiltonian equations

$$\frac{dx}{dt} = \frac{\partial U}{\partial \xi}, \text{ \&c.,} \quad \frac{d\xi}{dt} = -\frac{\partial U}{\partial x},$$

where $x, y, \ldots$ are generalised coordinates, $\xi, \eta, \ldots$ generalised momenta, and

$$U = \tfrac{1}{2}(\xi\xi)\xi^2 + (\xi\eta)\xi\eta + \ldots + V \quad \ldots \ldots \quad (1)$$

and V, $(\xi\xi)$, $(\xi\eta)$, &c., are any functions whatever of $x, y, \ldots$

We may regard a *granular medium* as a particular kind of system coming under this heading for which U takes the form

$$U = \Sigma \frac{\xi_r^2 + \eta_r^2 + \zeta_r^2}{2m_r} + \Sigma\Sigma_{rs} F_{rs}\{[(x_r - x_s)^2 + (y_r - y_s)^2 + (z_r - z_s)^2]^{\frac{1}{2}}\} \quad (2)$$

where m_r stands for any constant (being the mass of the rth particle, atom, corpuscle, grain, or whatever else you like to call it) and F_{rs} is any function whatever, continuous or discontinuous, determined by the law of force between different masses.

What I want to know is this:—

(1) Is every dynamical system which can exist in Euclidean three-dimensional space transformable into a granular system according to the above definition by a proper choice of coordinates?

(2) If not, what are the precise mathematical conditions under which a dynamical system can be so transformed?

We may put these questions in a somewhat different form. It is undoubtedly possible to conceive a universe the physical phenomena of which are represented by equations of any assumed form whatever, and therefore not necessarily by the equations of dynamics. Is it possible to conceive a universe the physical phenomena of which *are* represented by dynamical equations, but cannot be accounted for by means of a granular medium? I have read many treatises and essays dealing with theories of the ether, in which it has been tacitly assumed that the only possible answer to (1) must inevitably be "yes," and I cannot but feel that a discussion in your columns might be of much use to physicists.

G. H. BRYAN.

Phosphorescence of Photographic Plates.

I OBTAINED the following results, which are new to me, in the course of some experiments on the action of light on the salts of silver.

I have not yet thoroughly examined the light or radiation emitted in these experiments, but its actinic power is low, and it appears to render the brush discharge from an induction coil more luminous.

The sensitive silver salts, such as the bromide, iodide and chloride, if precipitated and kept in the dark, have the property, under certain conditions, of emitting light in degrees proportionate to their sensitiveness. Thus the bromide, which is the most sensitive, emits more light than the iodide and chloride. A convenient way of observing the phenomenon is to take a bromide photographic plate and place it at once (*without* having exposed it) in ordinary pyro soda developing solution and allow it to remain for ten minutes. Take out of the solution, wash, extinguish the "red lamp," and in total darkness plunge it suddenly into a dish containing a saturated solution of aluminium sulphate. The plate immediately becomes phosphorescent, and the solution also is luminous, but not so bright as the plate is at first. The light gradually weakens, and in a minute or two dies away. On pouring the solution off the plate into a bottle, the whole body of the liquid becomes luminous, and has the appearance of "bottled moonlight." It remains so several minutes, and the light is increased by shaking the liquid.

If half the plate be exposed to the action of white light for a second before treating with the pyro soda solution, that half remains dark and emits no light when the plate is put into the aluminium sulphate. If the plate is given a short exposure in the camera, and developed and put into the aluminium sulphate solution, the image will appear dark on a phosphorescent background.

On placing some precipitated bromide of silver (which had been kept a few days in a corked test-tube in the dark) in a porcelain dish and exposing it to a bright red light whilst adding the pyro-soda solution, it appears black, but on pouring off the solution the precipitate gradually assumes a bright green appearance under the red light, whilst in white light it appears dark grey or black.

The remarkable part of these experiments appears to me to be the fact that the exposing of the silver salts to the action of light destroys their power of emitting it under the treatment described, whilst the salt precipitated and treated in total darkness emits light freely.

T. A. VAUGHTON.

Ley Hill House, Sutton Coldfield.

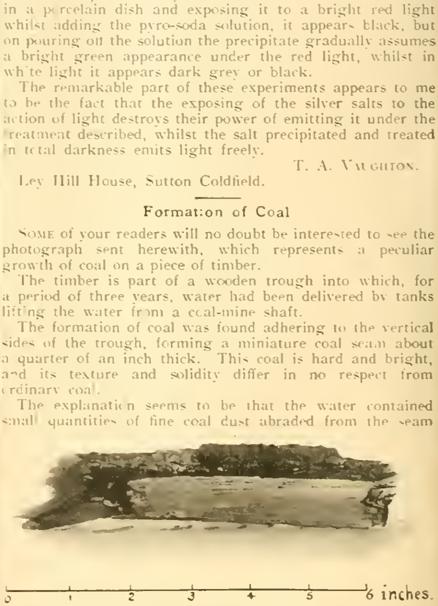
Formation of Coal

SOME of your readers will no doubt be interested to see the photograph sent herewith, which represents a peculiar growth of coal on a piece of timber.

The timber is part of a wooden trough into which, for a period of three years, water had been delivered by tanks lifting the water from a coal-mine shaft.

The formation of coal was found adhering to the vertical sides of the trough, forming a miniature coal seam about a quarter of an inch thick. This coal is hard and bright, and its texture and solidity differ in no respect from ordinary coal.

The explanation seems to be that the water contained small quantities of fine coal dust abraded from the seam



below, and these, either through the motion of the water or by some other means, were filtered out and formed anew into solid coal.

I believe this phenomenon has never previously been observed, and it appears to show that a coal seam may be broken up, washed away, and again built up in a new position without the aid of either the passage of time, pressure or heat. HENRY HALL.

Rainhill, January 3.

The Lamprey.

I SHALL feel obliged to any of your readers who will kindly tell me where to procure specimens of the lamprey. They are unobtainable at the Marine Stations of Millport and Plymouth. J. PENTLAND-SMITH.

St. Regulus, Park Place, Elie, N.B., January 5.

EARTH STRUCTURE.[1]

IN a copiously illustrated volume Mr. T. Mellard Reade, the well-known author of the "Origin of Mountain Ranges," expounds his views on certain geomorphological changes of profound interest to geologists. By tumefaction, wrinkling and denudation, the features of the face of our world are ever changing.

Evidences of the former activity by which regions of vast extent have been elevated or depressed almost vertically are, for example, found in raised sea beaches and submerged valleys. Fossiliferous rocks high up in mountain ranges, as in the Alps and Himalayas, attained their present positions by wrinkling during the process of mountain building.

Sedimentation results in the filling up of depressions, but its weight, no matter how mobile the undercrust may be, is not, according to the author, sufficient to raise neighbouring areas. Also it must not be overlooked that the phenomena presented to us represent pulsatory movements by which large tracts have been alternately raised and lowered. Secular contraction, inasmuch as it acts in one direction, does not seem adequate to explain these regional breathings. If by this and other well-known hypotheses we fail to explain vertical elevations and depressions, Mr. Reade invites us to consider the following.

We live on a rocky crust some thirty miles in thickness which rests upon a shell of igneous magma. By the expansion or contraction of portions of this magma due to changes in its temperature, tracts of the superincumbent crust are raised or lowered. The first question we are inclined to put relates to the manner in which these assumed variations in temperature are brought about. Blanketing by deposition of sediments the author regards as insufficient, but that there are such local subterranean alterations in temperature is evidenced by the shifting of volcanic centres and the intermittent activities of the same.

Variations in the character of lavas which have issued from the same vents, but at different times, indicate chemical and mechanical changes in a subjacent magma, and with such changes heat may be evolved or absorbed, and a magma may increase or decrease in its volume. Attention is also directed to the remarkable chemical and mineralogical alterations and the accompanying volumetric changes which have taken place in rock masses. With the phenomena of recalescence and magnetisation, alterations in bulk take place. In short, "the earth is not an inert mass cooling in space," but it is a planet within which there is flux and reflux, action and reaction, mechanical, chemical, and other activities in operation which result in the evolution of heat and alterations in volume, and in the latter we are to look for the cause of vertical elevations and depressions. References to the effect of these displacements in altering the level of oceanic water are made. The swelling or contraction of a magma beneath an ocean bed must result in a general rise or fall of water on the land.

The second form of geomorphic change considered is that which is due to a tangential creep and ridging of sediments due to fluctuating increases in temperature, and consequent expansion brought about by sedimentation. The wrinkles or mountain ranges on the face of the world are the results of such changes. With a falling temperature contraction sets in, strata shorten, and tensions result in faulting. By the faulting, wedge-shaped blocks fall inwards to act like keystones for the material on their flanks. The old theory that the features of the world are largely due to a shell accommodating itself to a retreating nucleus also accounts for the formation of the wrinkles by compression, but, unlike the theory advocated by Mr. Reade, it does not provide an explanation for normal faults which partition the roof of the world into block-like masses. That continental outlines are due to subsidences of the neighbouring oceanic basins, and are therefore sketched out by fault lines, is, according to the author, very doubtful; at all events, evidences of such dislocations, we are told, remain to be discovered. His own view is that for the most part such outlines are defined by mountain ranges, which represent thick accumulations of detritus derived from the denudation of land areas, lifted up by expansion on the platforms where they were deposited.

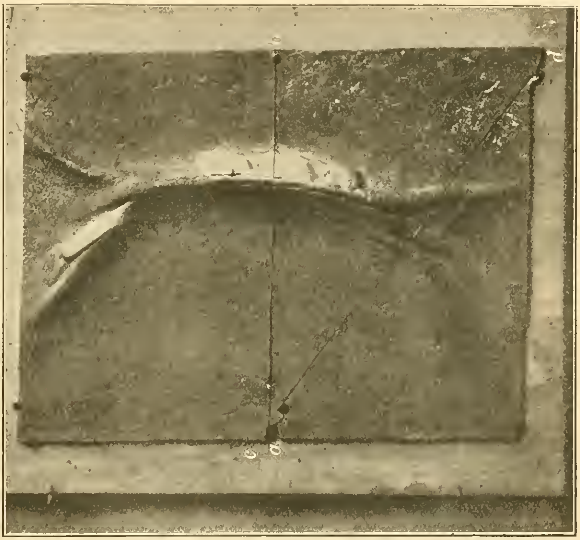

FIG. 1.—Showing cumulative effects of changes produced by hot and cold water upon a lead plate forming the lining of a pantry sink. A section along a, b, is shown in Fig. 2. (From "The Evolution of Earth Structure.")

A large section of the work refers to observations and experiments which throw light upon the foregoing hypotheses. The effects of end pressures as applied to layers of sheet lead, bars of soap, damp sand, and other materials are already fairly well known. An anticlinal rises near to the source of pressure, but the foldings are not altogether in accordance with those observed in nature. The effects of thrust are not con-

[1] "The Evolution of Earth Structure, with a Theory of Geomorphic Changes." By T. Mellard Reade. Pp. xv+342. (London: Longmans and Co., 1903.) Price 21s. net.

veyed to a sufficient distance, and Mr. Reade points out that, with similarly applied forces, something similar should occur in the earth's crust.

Results more in accordance with structures noted by the geologists are, however, seen in the effects of pressure originating in the general expansion of stratified material.

An observation bearing upon this form of action, which extended over many years, refers to the cumulative effects of changes produced by hot and cold water upon a lead plate forming the lining of a pantry sink. First it ridged up to form an overfold and eventually cracked. The fold was cut out, bent down, and soldered. In eight years' time the fold had again grown, little by little, by material imperceptibly flowing to the site of the fold, until it resembled the model of a mountain range.

The crescentic form of this ridge is seen in Fig. 1, the centre of the discs, but one on the right and the other on the left of a diameter. By placing cores upon the bed plate, or by deforming the bottom disc of clay upon which the other discs are placed, centripetal pressure results in anticlinals, spiral folding, various forms of shearing, and other structures, each being dependent upon the bias given by the form of the core, and it is to multilateral pressures akin to those employed in his experiments that the author ascribes many of the forms met with in mountain ranges.

Other interesting chapters relate to the effects of expansion due to atmospheric changes in temperature as exhibited by asphalt, cement, rails, and other substances, the production of slaty cleavage, and the supposed permanence of oceanic basins and continental domes.

The effects of denudation as a factor playing an important part in shaping the features of the world are

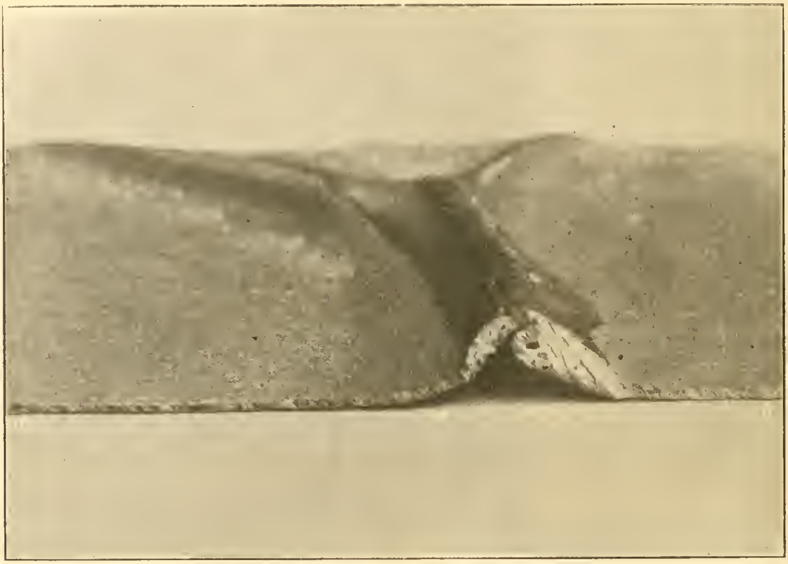

FIG. 2.—Photograph of section along saw-cut line a, b, Fig. 1, showing structure of the fold and overfold. (From "The Evolution of Earth Structure.")

whilst a section of the same through a, b (Fig. 2) shows that it had become an overfold. It is a form that could not be produced by external pressures, and as it so closely accords with the theory it is intended to illustrate, it well deserves the space, which is that of a whole chapter, devoted to its history.

Torsional structures, as, for example, those noted in the dolomites, and the curved axes of mountain ranges met with in nature, may be explained by multilateral or circumferential pressure, particularly when it is assumed that an initial bias is given by the form of the floor on which the strata have been deposited.

Experimental demonstrations of the effects of this form of pressure were made by compressing discs of clay confined by a circular metal loop, the diameter of which could be altered, much in the same manner that the diameter of a loop in a piece of string may be altered by pulling on the two ends. The ordinary effect of converging pressure is to produce doming, not in hardly mentioned, the reason being that they have already received so much attention from other writers. Mr. Reade deals almost entirely with activities which are hypogenic, and these, although some of them may be old acquaintances, he presents to geologists in a manner so novel that they acquire an importance which most certainly they did not previously possess. The ancient contraction theory is to be largely supplanted by one of expansion and contraction.

The amount of vertical movement asked for may be taken at 10,000 feet, or 1/2000 of the earth's radius —to human beings a quantity that is stupendous, but when regarded as a deviation in the smoothness of our globe it becomes a quantity that is insignificantly small. The author will no doubt find many followers; some may hesitate, but even those who have crystallised an ancient faith will pause to think and give to originality the consideration it deserves.

J. MILNE.

THE SANTA CRUZ FAUNA AND THE PRINCETON EXPEDITION TO PATAGONIA.[1]

IT is with the greatest satisfaction that we welcome the first-named instalment of an important work. The Santa Cruz Tertiary mammalian fauna is one of the most interesting and remarkable in the world, and we have now, for the first time, a guarantee that it will be described in a manner worthy of its importance. Hitherto this wonderful fauna has been but very scantily represented in museums outside of the Argentine, and in consequence students could gain only a very imperfect idea of its extent and affinities owing to the majority of the descriptions being of a more or less preliminary nature and inadequately illustrated. The acquisition by the Princeton Museum of the very large series of specimens collected by the expeditions to Patagonia under the charge of Mr. J. B. Hatcher from 1896–1899, together with a careful survey of all the other known collections, has now rendered it possible to publish full and adequate descriptions of all the more important types, and through the liberality of Mr. J. Pierpont Morgan the work will not be cramped for lack of illustrations.

In the introductory chapter, Prof. Scott, whose name is a sufficient guarantee for the excellence of the work, states that it has been decided to describe the specimens with a degree of detail which would be unnecessary in the case of forms well represented in museums throughout the world, and this detail will render his treatment of the work practically exhaustive. Some idea of the magnitude of the task will be gathered when we state that the present fasciculus of 106 4to pages is devoted entirely to the armadillos.

From the general character of the Santa Cruz fauna Prof. Scott is of opinion that Miocene Patagonia was rather an outpost of the South American fauna than the main area of its development. So far as the Edentates are concerned, this statement is justified by the apparent absence from the Santa Cruz horizon of representatives of the true sloths and anteaters, which, judging from the comparatively slight differences between the Santa Cruz Edentates and their Pampean successors, must almost certainly have been in existence at the epoch in question. This view is strengthened by the circumstance that many of the modern types of armadillos are unrepresented by ancestral forms in the Santa Cruz formation.

In general the Santa Cruz armadillos may be said to have attained the modern degree of specialisation, although in many details primitive features are retained. None of them, for instance, have an anterior solid shield to the carapace, which consists in most cases entirely of movable bands, although in certain instances a pelvic shield is developed. The most aberrant type is the horned Peltephilus, which has a full series of front teeth. The reference to this genus of a humerus of a somewhat monotreme-like type is not supported by the Princeton collection. Following the lead of other American zoologists, Prof. Scott splits up the Edentata into a larger number of family and generic groups than has generally been the fashion in this country, the number of such divisions being, of course, largely a matter of individual opinion. Prof. Scott, it will be noticed, has no hesitation in regarding the Santa Cruz fauna as of Miocene rather than of Eocene age.

The collection and description of the fossil mammals and birds, although the prime, was by no means the sole object of the expedition, and, according to a provisional scheme issued by the publication committee, it is intended to issue a full account of the zoology, palæontology, botany, and geology of the districts traversed. In this scheme it was proposed to complete the work in six volumes of about 500 pages each, and to do this within a period of four years. Apparently, however, this scheme proved inadequate, for in place of the botany forming a portion of vol. i., we find the sections before us constituting the first part of an eighth volume, the whole of the first being devoted to the narrative of the expedition and geography.

With regard to the botany, a very brief notice must suffice. The general characters of the vegetation of western Patagonia are described by Prof. Dusèn, who directs attention to the sharp demarcation between the evergreen and the deciduous beech-forests respectively characterising the two slopes of the Cordillera, and also between the whole forest tract and the Patagonian steppe. The Bryophyta are described by the same writer, but the Hepaticæ are treated by Mr. Evans and the Pteridophyta by Mr. Macloskie.

The bulky and beautifully illustrated volume devoted to the narrative of the expedition and geography teems with interest, but here, again, limitations of space prevent our doing justice to its contents. Perhaps the most generally interesting section is the one describing the Tehuelche Indians and their mode of life, which contains a number of most excellent portraits of these interesting tribes, as well as illustrations of the manner in which guanaco robes and other articles are manufactured. Judging from plate l., the Tehuelche girls are far from uncomely, but, as shown in the preceding plate, there is a sad falling off in personal appearance with advancing age.

So far as it is yet advanced, the work is an excellent example of the thoroughness of modern American treatment of scientific subjects. R. L.

PROF. KARL ALFRED VON ZITTEL.

GEOLOGISTS and biologists throughout the world will lament the death of Prof. K. A. von Zittel, the accomplished palæontologist of Munich. For more than thirty years he had been acknowledged as the leading exponent of the science which is intimately connected with the progress both of geology and biology. For a still longer period his charming personality had combined with his wide reputation to attract to the Palæontological Museum at Munich students of the natural sciences from all civilised nations. Those who were unable to follow the prescribed university course were at least frequent guests, taking advantage of the unrivalled facilities for study and research among fossils which the professor's laboratories and collections afforded. So highly appreciated, indeed, was the school of palæontology in Munich that Prof. von Zittel soon began to experience the practical sympathy of several of his wealthy fellow-citizens, who had learned of his fame. In this manner he was provided with funds to equip expeditions and purchase collections of fossils beyond the means of most institutions of a similar character. The result was that the Palæontological Museum in the old Academy of Munich, already fine when von Zittel became professor, rose to preeminence among the museums of the European continent. It began to illustrate not only Bavaria and Europe, but every part of the world from which fossils were known; and as the collections were acquired, descriptions of all the important novelties were always quickly published, usually prepared by some student-graduate working under the professor's direction.

Prof. von Zittel had the advantage of beginning his great life-work at the early age of twenty-seven. Born at Bahlingen, in Baden, on September 25, 1839, he completed his education in the Universities of Heidelberg, Paris, and Vienna, and in 1863 he became teacher of geology and mineralogy in the polytechnic at Carlsruhe. In 1866 he succeeded Oppel as professor of geology and palæontology in the University of Munich. At this time he was interested in questions of stratigraphical geology, which depended much on the accurate determination and comparison of fossils. He had already written two important memoirs on the bivalved shells from the Cretaceous Gosau formation, which had been published by the Vienna Academy. He was then beginning to study the so-called Tithonian formation, on which he issued an important memoir in 1870, determining that it was equivalent to the Purbeck and Wealden formations of western Europe. These and other researches of a similar nature gradually impressed upon von Zittel the necessity for a fundamental revision of the whole science of palæontology, as it was then understood, and the preparation of a comprehensive treatise on the subject which could be used as a work of reference. He accordingly planned his now famous "Handbuch der Palæontologie," which was begun in 1876 and completed in four volumes in 1893, and this was the systematic basis of nearly all his future research. He thoroughly studied the fossil representatives of each group of the animal kingdom in order from the Protozoa to the Mammalia, and his original observations were not only incorporated in the "Handbuch" itself, but also formed the subject of many special papers and memoirs. Quite at the beginning of his task he met with unusual difficulties in the classification of the sponges, which necessitated his abandoning the projected treatise until he had devoted three years to his classical "Studien über fossile Spongien," which were published by the Royal Bavarian Academy between 1877 and 1879. Almost simultaneously with the early work of Sollas in the same direction, von Zittel devised a means of studying the fossil sponges in thin sections under the microscope, and his novel researches eventually led to a systematic arrangement of the Porifera, which has been confirmed in all its essential features by subsequent investigations of both extinct and living forms. Some of his memoirs related even to the Vertebrata, and those on the Chelonia and Pterodactyls from the Lithographic Stone of Bavaria (*Palaeontographica*, 1877, 1882) are especially valuable contributions to science.

On occasional excursions Prof. von Zittel still devoted himself to purely geological work, and among his published observations may be particularly mentioned those on the glaciation of the plain between Munich and the Alps, made in 1874 and 1875. Only in one instance, however, did he undertake researches of a geological nature on a large scale, namely, when he accompanied the Rohlfs Expedition to the Libyan Desert in 1873-74. The important results of these investigations were presented to the Royal Bavarian Academy as a "Festrede" on March 20, 1880, and a more detailed report (reprinted from the *Palaeontographica*) was issued as a separate work in 1883 under the title "Beiträge zur Geologie und Palæontologie der Libyschen Wüste." In this volume von Zittel's geological treatise was supplemented by a series of detailed descriptions of the fossils by Fuchs, Mayer-Eymar, Schenk, and other palæontologists.

The *Palaeontographica*, to which reference has been made, is a serial devoted solely to illustrated memoirs on fossils, founded by the eminent German palæontologists W. Dunker and Hermann von Meyer in 1846. From 1869 until his death Prof. von Zittel was its responsible editor. The Munich school was thus provided with ample means for publishing palæontological researches, and the editor's former pupils have for many years been the principal contributors to its pages. Although Prof. von Zittel himself was the main factor in the production of many of these memoirs, he always regarded his share as merely that of a helpful teacher, and did not overshadow the plodding student by adding his own name as joint author.

For the purposes of elementary or less specialised teaching the professor published a large and valuable series of lecture-diagrams of palæontology ("Palæontologische Wandtafeln," 1879–91), and as soon as his great "Handbuch" was finished he began at once to prepare an up-to-date epitome of it in one volume, which appeared in 1895 as the "Grundzüge der Palæontologie." Von Zittel also sometimes attempted more popular writings, such as his little readable volume on rocks and fossils, named "Aus der Urzeit," which appeared in 1872, with a second edition in 1875. This work contained some interesting maps of the distribution of land and sea in Europe during the various Mesozoic and Tertiary periods. His last essay of general interest was an address on "Palæontology and the Biogenetic Law," read before the International Congress of Geologists in 1894 and published in English in *Natural Science*, May, 1895.

The address just mentioned was almost the only occasion on which Prof. von Zittel ventured to express any opinions on the philosophy of biology or the solution of fundamental problems. Apart from his brilliant researches on sponges, indeed, scarcely any of his work can be regarded as suggesting important novel points of view. His "Handbuch" contains innumerable new facts obtained by personal observation, and they are accompanied by many proposed changes in classification or nomenclature, but only a small proportion of these emendations have proved acceptable to those who have pursued later research. His comprehensive treatment of palæontology has stimulated the progress of the science and has been of immense value, not because it suggests problems, but because it is a monument of judicious industry and thoroughness in the collection and presentation of the known facts. Von Zittel's "Handbuch" is indeed a trustworthy dictionary for reference rather than a guide to profitable lines of inquiry; and when the Americans, under the direction of Dr. C. R. Eastman, attempted a few years ago to infuse more philosophy into an English edition of the section Invertebrata of his "Grundzüge," Prof. von Zittel did not hesitate to express his dissent in conversation. A second edition of the first part of the "Grundzüge" has just appeared, in which none of the American palæontologists' changes are admitted. To understand the author's position it is only necessary to quote a sentence from his address of 1894:—"An important part is played to-day by subjective opinions, and when I think of the anxiety with which we elders—we who received our scientific education before the Darwinian era—proceeded to found a new species or genus, and compare it with the light-hearted manner in which to-day species, genera, families, and orders are set up and again put down, I am herein most forcibly impressed by the difference between then and now. The domination of the Linnæan and Cuvierian principles threatened systematic biology with soulless paralysis: the unbridled subjectivity of recent times may easily lead to anarchy."

A very striking instance of Prof. von Zittel's tireless industry in judicious compilation is his valuable "Geschichte der Geologie und Palæontologie bis dem Ende des 19ten Jahrhunderts," published by the Royal

Bavarian Academy in 1899. This volume was translated into English by the author's distinguished pupil, Mrs. Maria Ogilvie-Gordon, and issued in a slightly abbreviated form in Mr. Walter Scott's Contemporary Science Series in 1901. It will always remain a standard work of reference.

Prof. von Zittel naturally received numerous honours. Many years ago he became a Privy Councillor, and from 1899 until his death he was president of the Royal Bavarian Academy of Sciences. He was elected a foreign member of the Geological Society of London in 1889, and received the Wollaston medal in 1894. He was made a foreign associate of the United States National Academy of Sciences in 1898, and a correspondant of the Paris Academy of Sciences in 1900. His greatest joy was the ardent friendship with which he was honoured by his former pupils scattered through nearly all the civilised nations of the globe.

A. S. W.

NOTES.

The fifth International Congress of Zoology, held at Berlin in 1901, selected Switzerland as the place of meeting for the sixth session, and elected Prof. T. Studer president. In accordance with this resolution, the congress will meet at Bern from August 14–19 of this year. Prof. Studer, Bern, is president of the general committee, and the vice-presidents are:—Prof. E. Beraneck, Neuchâtel; Prof. H. Blanc, Lausanne; Dr. V. Fatio, Geneva; Prof. L. Kathariner, Fribourg; Prof. A. Lang, Zürich; Prof. E. Yung, Geneva; Prof. F. Zschokke, Basel; and Prof. R. Blanchard, Paris. The secretaries are Prof. M. Bedot, Geneva; Dr. J. Carl, Geneva; and Dr. W. Volz, Bern. The general meetings will be held in the Palace of Parliament at Bern, and the sectional sittings in the new university. During the congress there will be an excursion to Neuchâtel and to the Jura lakes, in order to visit the lake-dwellers' settlements. The closing meeting of the congress will be held at Interlaken. Afterwards the members of the congress will be invited to visit other Swiss cities. Communications or inquiries referring to the congress should be addressed to the president of the Sixth International Congress of Zoology, Museum of Natural History, Waisenhansstrasse, Bern. The congress is open to all zoologists and to all who are interested in zoology.

The *Atti* of the Lincei Academy announces the death, on November 25, of Angelo Maffucci, a member of the Academy since July, 1900.

A new Pasteur Institute has, says the *British Medical Journal*, been established at New Orleans, where the antirabic treatment will be carried out without any expense to the patients.

It is announced that Dr. Felix Kanitz died at Vienna on January 5. Dr. Kanitz, who was born at Budapest in 1829, was well known for his archæological and ethnographical labours in the Balkan peninsula.

It is reported that the Goodwin Sands lightships are to be put in communication with the shore by means of wireless telegraphy, and that the installation is to be completed in about a month. Four lightships will communicate with the Admiralty wireless telegraphy station near Shakespeare Cliff, Dover.

Lieut. E. H. Shackleton, late third lieutenant of the *Discovery*, and one of the three men who reached furthest south in a journey from the ship, has been appointed secretary of the Royal Scottish Geographical Society in succession to Lieut.-Colonel F. Bailey. Lieut. Shackleton had to be invalided home from the Antarctic on account of hæmorrhage of the lungs.

The death is announced of Dr. F. von Hefner-Alteneck, a member of the Berlin Academy of Sciences and a well-known engineer. Dr. von Hefner-Alteneck was born at Aschaffenburg in 1845. After studying at Munich and Zurich he entered the firm of Siemens and Halske, with whom he remained until 1890. He became chief engineer of the firm, and was the inventor of many electric appliances produced by that house.

The Geological Society of London has this year awarded its medals and funds as follows:—the Wollaston medal to Prof. Albert Heim, of Zurich; the Murchison medal to Prof. G. A. Lebour; the Lyell medal to Prof. A. G. Nathorst, of Stockholm; the Wollaston fund to Miss E. M. R. Wood; the Murchison fund to Dr. A. Hutchinson; the Lyell fund to Prof. S. H. Reynolds and Dr. C. A. Matley; the Barlow-Jameson fund to Mr. H. J. L. Beadnell.

Baron Erland Nordenskjöld, who left Southampton on January 6 on an expedition to Bolivia, informed a representative of Reuter's Agency that the expedition would last at least eighteen months, as he intended to penetrate the northern forests of Bolivia for the purpose of studying the hostile Indian tribes along the various tributaries of the Amazon, and the region to be traversed was practically unknown. He is accompanied by Lieut. D. de Bildt, a son of the Swedish Minister in London, and Dr. Holmgren.

At a meeting on January 5, the Bath City Council had under consideration a letter from the National Trust relative to the quarrying in the Cheddar Cliffs, and unanimously adopted the following resolution:—"That this council has heard with sincere regret of the damage which is being caused to the Cheddar Cliffs by the quarrying of stone therefrom, and other works connected with such quarrying, and trusts that steps may promptly be taken for preserving in its original condition, so far as practicable, this most picturesque and interesting feature of the West of England." Similar resolutions have also been passed by the Somerset County Council and other public bodies in the district.

Dr. Nordenskjöld and the members of his South Polar Expedition arrived at Hamburg on January 6. The unexpectedly early return from the South Polar regions of this expedition has, the *Times* states, enabled Dr. Jean Charcot to recast the plans of the French expedition on board the *Français*. He now proposes to explore the west coast of Graham Land and to carry out a very exhaustive scientific investigation of that region. From Flanders Bay, at the south-west end of Belgica Strait, Dr. Charcot intends to push south in the direction of Pitt Island and Adelaide Island, with Alexander Land as the great goal of the expedition's efforts. With the return of the Antarctic spring, if winter quarters have been taken up far enough south, Alexander Land will be the objective of these parties; otherwise the excursions will be undertaken with the object of linking up the work of the French expedition with that which Dr. Nordenskjöld and his companions have accomplished, working from the other, or eastern, side of the land masses in this part of the Antarctic region. It is Dr. Charcot's definite intention to return at the end of the season of 1904–5. The *Français*, indeed, is only provisioned for two years, and Dr. Charcot states that if the expedition does not return in the early months of 1905, it must be concluded that they have been involuntarily detained, and a relief vessel must be dispatched to their assistance.

THE Board of Education, in cooperation with the council of the Society of Arts, intends during the present year to hold, in the Victoria and Albert Museum, South Kensington, an exhibition of engravings produced by mechanical means, such as photogravure and other photographic processes, as a sequel to the exhibition of engraving and etching held during last summer; and as great advancements have been made in printing in colours since the Exhibition of Modern Illustration in 1901, specimens of colour printing will be included. A committee, of which Sir William de W. Abney, K.C.B., F.R.S., will act as chairman, has been formed to advise the Board in carrying out the exhibition. All communications should be addressed to the secretary, Exhibition of Mechanical Engraving, Board of Education, South Kensington.

AT the monthly meeting of the Church Society for the Promotion of Kindness to Animals, held on Friday, January 8, at the Church House, Westminster, it was resolved to present a memorial to the Government asking for a departmental inquiry into the conditions under which slaughtering is carried on, and the general treatment of animals. A paper was read on "Nature-Study Conducive to Kindness to Animals" by the Rev. Claude Hinscliff.

MR. J. A. GILRUTH, pathologist to the Public Health Department, Wellington, N.Z., is reported to have made a new discovery with regard to anthrax (*Times*, January 11). The series of experiments which he has conducted proves that an animal particularly susceptible to anthrax, such as a guinea-pig or a rabbit, will resist enormous doses of virulent anthrax provided the anthrax germs be mixed with a greater quantity of another species of microbe that in itself must be non-pathogenic and incapable of producing any disease. These observations may ultimately prove to be of practical importance, and their confirmation will be awaited with interest.

PROF. A. KLOSSOVSKY, of the University of Odessa, and director of the meteorological system of south-west Russia, has published in vol. xxv. of the *Journal* of the New Russian Society of Naturalists a very interesting *résumé* of the general condition of weather prediction at the present time. He deals with the old method of mean values and the modern method of synoptic meteorology, the application of mathematical analysis, with periodicities (varying from two to thirty-five, and even one hundred and thirty-five years), the moon's influence, &c. The chief object of the paper is to examine the method of M. Demtschinsky and the predictions published for some years in the journal *Climate*. The predictions in question have been submitted to an exhaustive examination, and Prof. Klossovsky's conclusions are entirely unfavourable to M. Demtschinsky's method and results. For the benefit of meteorological students the author suggests that, if M. Demtschinsky persists in his views, the matter should be referred to the independent decision of the International Meteorological Committee, and that the necessary funds should be placed at its disposal for the preliminary work of calculation and preparation of diagrams.

EVERY photographer who washes his negatives carefully is aware of the great expenditure of water and time required before he is satisfied that the last trace of hyposulphite of soda has been dissolved. Four hours is sometimes given as the length of time necessary, but usually one hour is considered sufficient. Mr. J. Norton, in the *British Journal of Photography* (January 1), suggests an alternative scheme for getting rid of the hypo in five minutes, and as he says he has given some attention to this question, his process may be summarised here. The basis on which the suggestion is made is that barium chloride has an exceedingly strong affinity for sulphur. On the addition of barium chloride to hyposulphite of soda both are immediately broken up; the barium unites with the sulphur and the soda with the chlorine, so that the products are barium sulphate and common salt. The barium sulphate being loose, very heavy, white (poisonous) powder, quite insoluble, can be easily rinsed off the photographs, and the common salt remains in the solution. After the photograph has been taken from the hyposulphite of soda solution, it should be rinsed in running water for a minute and rubbed on both sides with a cotton swab. It should then be dipped for two minutes in a 5 per cent. solution of barium chloride, and afterwards rinsed and swabbed in running water. Mr. Norton finds that five minutes is sufficient for this latter manipulation. He also remarks that the whites of the photographs are improved by this process.

Two small booklets on "Color Correct Photography" and "How a Lens Works," belonging to the "Photogram Series of Penny Pamphlets on Photography," have been received from the publishers, Messrs. Dawbarn and Ward, Ltd. The first contains some facts about isochromatic and orthochromatic methods which will aid the photographer to improve his work both from the technical and pictorial points of view. The second tells one what the lens can and cannot do, and gives in simple language various pieces of information useful to a beginner. This useful series of pamphlets will no doubt find many readers.

AN account of the development of mathematics during the nineteenth century is contributed by Dr. J. T. Merz to the *Proceedings* of the Durham University Philosophical Society.

IN a paper contributed to the *Physikalische Zeitschrift*, iv., 30, by Messrs. R. Luther and W. A. Uschkoff on the chemical action of Röntgen rays on bromide-gelatin photographic plates, the authors arrive at the conclusions (1) that the action of these rays is specifically different from that of ordinary light; (2) that short exposure to Röntgen rays alters the sensitiveness of the plates to ordinary light, sometimes increasing and sometimes decreasing it; (3) that previous illumination with ordinary light does not affect the behaviour of bromide plates towards Röntgen rays.

SEVERAL papers have recently appeared dealing with the study of ultra-microscopical particles. In the *Revue générale des Sciences* MM. A. Cotton and H. Mouton give a general account of the recent researches of Siedentopf and Zsigmondy, and Mr. E. Raehlmann, of Weimar, contributes to the *Physikalische Zeitschrift* the results of his researches on the ultra-microscopic particles contained in solutions of colouring matters, these researches having been carried out with the aid of the instrument belonging to the Zeiss Laboratory in Jena.

THE recent attempts of engineers and others to grapple with thermodynamical problems falling more strictly within the domain of the physicist have led to the publication of a paper by Prof. W. S. Franklin in *Science* for November 20, 1903, on the misuse of physics by biologists and engineers. In discussing irreversible processes, the author introduces the new nomenclature of "steady sweeps," "trailing sweeps," and "simple sweeps," and he maintains the view (rightly or wrongly) that the conception of *temperature* has no meaning except in cases of thermal equilibrium.

FROM the Gesellschaft für drahtlose Telegraphie we have received reprints of papers from the *Elektrotechnische Zeitschrift* dealing with a new detector for wireless telegraphy and a new measurer for electric waves. The detector, which is described by Mr. W. Schloemilch, depends on the property that when electric waves fall on a polarised electrolytic cell placed in circuit with a source of current of slightly higher E.M.F., the current in the circuit is increased either owing to a decrease of the resistance due to polarisation or from some other cause. The name "System Telefunken" has been given to this new method of wireless telegraphy.

IN *Science* for December 18, 1903, Dr. G. F. Kunz and Prof. C. Baskerville describe a series of observations made on the conduct of the gems and gem material of the Tiffany Morgan collection, and on several other collections of diamonds, under the influence of radium, Röntgen rays, and ultra-violet light. The fluorescence and phosphorescence were tested for more than 13,000 verified minerals. Seeing that three different kinds of radiation are considered, and that a mineral may respond or fail to respond to any one of them, the "number of ways" (to quote the familiar question on permutations) is eight, and the authors propose a tentative classification of minerals based on these eight ways. It is further pointed out that we have here a series of discriminating tests which may be readily applied to various minerals with the use of comparatively simple apparatus.

ON March 16, 1882, the late Prof. Adolfo Bartoli communicated a sealed packet to the Accademia dei Lincei, of Rome. This packet was opened at the meeting of the mathematical and physical section on February 1 of last year, and found to contain a paper on the transformation into electric currents of the radiations falling on a reflecting surface in motion. In this paper, which is published in the *Atti dei Lincei*, xii., 9, the author discusses a method, previously described, of conveying radiation from a cold body to a hot one by means of deformable reflectors, and among the various kinds of forces necessary to reconcile this result with thermodynamics, the author suggests pressure due to radiation, and the production of tangential currents when a reflecting surface is rotating rapidly in sunshine. It is interesting to note that the first explanation, which is now well established, led in Bartoli's time to no conclusive results, while his experiments clearly indicated the existence of the currents required for the second explanation.

A LIST of the flora of the Valle Anzasca (Macugnaga), on the Italian side of Monte Rosa, is given by M. Francesco Ardissone in the Lombardy *Rendiconti*. The valley in question, which is rarely if ever explicitly mentioned in botanical works, is remarkable for its large representation of the order Crassulaceæ, and in addition the author describes a new species of Androsace under the name *A. heterophylla*.

IN the *Memoirs* of the Boston Society of Natural History Prof. Jeffrey has published the first of a series of memoirs which will be devoted to the comparative anatomy and phylogeny of the Coniferæ. The genus Sequoia forms the subject of this paper, and considerable importance is attached to the distribution of the resin ducts. A similar distribution is found to occur in species of the genus Abies, whence Prof. Jeffrey is led to postulate the derivation of the living Sequoias from an abietineous stock.

THE experiment of fixing a seed to the side of a dish containing mercury so that the root of the seedling may force its way downwards into the mercury is a common one. It is not generally known that with certain seeds the penetration of the roots into the mercury may be effected without any fixation beyond the film of water which must be placed on the mercury to keep the root moist. In the *Proceedings* of the Amsterdam Royal Academy of Science Mr. P. van Harreveld discusses the controversies which have arisen out of this experiment, originally performed by Pinot in 1829. In a paper from the same source Dr. and Mrs. Th. Weevers bring forward evidence to show that alkaloids are formed synthetically in the young parts of such plants as tea, coffee, and cacao, and that in older parts they are wanting; the conclusion is that they are used up in metabolism.

HAVING regard to the present and future condition of the cotton industry in this country, very great interest attaches to the results of the trials which are being made to introduce the cultivation of cotton into our colonies. For the benefit of those disposed to take up cotton growing in the West Indies, the Imperial Commissioner of Agriculture has brought together in the last number of the *West Indian Bulletin* a series of articles dealing with the cultivation, chemistry and diseases of cotton. A point of primary importance is the careful selection of seed, for not only has the Sea Island cotton been improved by judicious selection, but the Rivers variety, which is resistant to the wilt disease, was obtained in the same way. Experimental plots were only started in St. Kitts, Antigua, Montserrat, and Barbados last year, so that it is too early as yet to obtain trustworthy data.

CAPTAIN STANLEY FLOWER has favoured us with a copy of the second edition of the "Guidebook" to the Zoological Gardens under his care at Giza, near Cairo. A brief account of many of the more interesting species in the collection is given. It is satisfactory to learn that the three specimens of the shoe-billed stork are still thriving.

THE January number of the *Entomologists' Monthly Magazine* contains several items of special interest. In one note Prof. T. H. Beare records the occurrence in two localities of a foreign beetle (*Ptinus tectus*) recently introduced into this country. The native home of this beetle is apparently Tasmania, but one of the introduced colonies came from the Levant. In another communication Mr. N. H. Joy records a Russian beetle, *Euconnus maeklini*, as British. Mr. W. E. Clarke, in recording several kinds of insects—chiefly moths—observed at the Eddystone Lighthouse, touches a practically new subject, namely, the wanderings and migrations of insects.

MR. P. W. STUART-MENTEATH has sent us a pamphlet on "Pyrenean Geology, part i., the Alpine Paradoxes" (Dulau and Co., 1903, price 1s.). This is a controversial essay on the structure of the Alps and Pyrenees, and on errors in the geological maps of those regions.

THE *Journal* of the Royal Microscopical Society for December, 1903, contains the usual summary of current researches relating to zoology and botany (principally Invertebrata and Cryptogamia), microscopy, &c., and in addition there is part xv. of Mr. F. W. Millett's report on the recent Foraminifera of the Malay Archipelago.

THE fossil echinoids of Japan have been described by Mr. S. Tokunaga (formerly Yoshiwara), the species being illustrated by four plates (*Journ.* Coll. Science, Tokyo, vol. xvii., art. 12, 1903). No echinoids have been found in the Palæozoic strata of Japan; the Mesozoic strata have yielded Pygurus, Toxaster, Cidaris, Pseudocidaris and Hemici-

daris (?); and eighteen genera are recorded from the Cainozoic series. Most of these last-named genera are still living, and some of the species have a wide geographical distribution and a considerable range in Tertiary time.

MR. A. LUCAS has prepared, for the Public Works Ministry at Cairo (1903), a report on the soil and water of the Wadi Tumilat lands. It appears that this alluvial tract formed part of "the land of Goschen," and was a fertile tract until ruined by the Ismailia Canal. The author points out that this high-level canal passes through a porous soil, and the seepage-water has not only raised the general level of the subsoil water, but has brought to the surface in many places salts of soda which have proved more or less injurious, the sodium carbonate being most harmful to vegetation. Wind also helps to distribute the efflorescent salts. The remedy consists in a thorough system of drainage, and in frequent washing of the land.

WE have received a copy of the "New and Revised Edition of a Geological Map of the Southern Transvaal," by Dr. F. H. Hatch (Stanford, price 20s. in sheet, 25s. in case), with explanatory pamphlet (1903). The scale of the map is a little more than four miles to an inch, and it includes an area bounded on the north by Pretoria, on the west by Ventersdorp and Klerksdorp, on the south by the Vaal River, and on the east by Greylingstadt and Heidelberg. It is very clearly printed in colours, and the farm boundaries are shown. Although admittedly a sketch-map, it will be of great service in representing the present state of knowledge with regard to the extent of the coal-bearing strata, the auriferous rocks and other mineral resources, not to mention the Dolomite series, which is economically of great importance as the source of perennial streams and as furnishing the present water-supply of Johannesburg.

SYSTEMATIC and distributional arrangements of the genus Polygonum in India have been prepared by Captain Gage, and are published in the *Records* of the Botanical Survey of India. The horizontal distribution of the species throughout certain sub-subareas of India compared with their distribution in other countries is well shown in one set of tables, and another set indicates the vertical distribution. From the latter it will be observed that *Polygonum viviparum* shows the greatest vertical range, namely, from 4000 to 17,000 feet; *Polygonum tortuosum* and *Polygonum sibiricum* reach to the same upper limit, but are not found below 11,000 feet.

IN the notice of "Le Point critique des Corps purs" in last week's NATURE (p. 217) it should have been stated that the author of the book is Prof. E. Mathias.

MESSRS. WATTS AND CO. have issued for the Rationalist Press Association sixpenny editions of "Science and Speculation," by Mr. C. H. Lewes, and of Mr. Edward Clodd's "Story of Creation." The latter volume contains eighty-six illustrations and tables.

THE Brin Oxygen Companies, the London address of which is now Elverton Street, Westminster, S.W., have issued a convenient little diary which is provided with much useful information. Not only are full particulars of the prices of the apparatus made by the companies and of the compressed gases supplied by them included, but also a series of hints to users of compressed gases in the form of medical notes, notes for lanternists, for blowpipe users, and on extreme refrigeration. In addition, the booklet contains a cylinder record and instructions for using liquefied carbon dioxide.

WE have just received an advance copy of Merck's English catalogue of fine chemicals. The list of chemicals is very comprehensive, and is probably the most complete published in this country. We note that Merck's present factory in Darmstadt will soon be replaced by entirely new works, now in course of erection.

IN the current number of the *American Journal of Science* Mr. J. C. Blake points out that soluble silver compounds are formed in the preparation of colloidal silver solutions by sparking between silver electrodes under water. It seems probable to the author that these compounds may play an important part in the peculiar actions exhibited by colloidal metal solutions, which, from the similarity of their behaviour to that of ferments, have been styled by Bredig inorganic ferments.

IN the *Proceedings* of the American Academy of Arts and Sciences Mr. G. P. Baxter describes some further experiments relative to the atomic weight of iron, an entirely new method—the analysis of ferrous bromide—being employed. These new experiments confirm the result, 55·88, previously obtained by Richards and Baxter for the atomic weight by the reduction of the oxide, and indicate that the value, 56·0, usually employed is appreciably inaccurate.

A NEW form of electrical resistance furnace was described by Dr. Frölich at the last meeting of the German "Bunsen" Society for Applied Physical Chemistry. Instead of employing carbon cores as the immediate source of heat, the sides of the furnace itself are utilised, the furnace being constructed of some specially suitable material the nature of which has not been divulged. The mean temperatures reached in a core furnace and in that described by the author under comparative conditions were found to be 1200° and 1600° C.

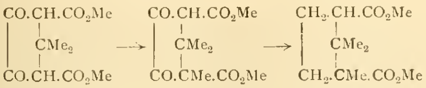
THE first number of a new review, the *Physikalisch-chemisches Centralblatt*, has just been issued. It is not intended as a medium for the publication of original work, but as a comprehensive centralising review of progress in physical chemistry, the extraordinarily rapid rise and development of which during the last decade is almost unique in the history of science. The abstracts are to appear either in German, English, or French, and, so far as possible, will be furnished by the authors themselves. The review will be issued twice a month, and will no doubt be a valuable aid to the numerous chemists who desire to keep abreast of physicochemical literature.

THE oxidation of phosphorus is a reaction which, in spite of its apparently simple nature, exhibits many anomalies. The rate of oxidation increases as the pressure diminishes, and no completely satisfactory explanation of this apparent exception to the law of mass action has yet been given. In the current number of the *Journal* of the Chemical Society Mr. E. J. Russell contributes a further series of observations on the subject. It appears that the presence of a small quantity of water is necessary for the oxidation, and that the quantity left after drying with sulphuric acid is that which allows reaction to proceed most rapidly. The results of experiments carried out at higher pressures contradict the usual statement that phosphorus only reacts with oxygen at low pressures, and the author finds that the reaction in these circumstances is in agreement with the mass action law.

A NOVEL reducing agent is described by Dr. Stoermer in a recent number of the *Berichte*. He has found that in a considerable number of cases compounds containing the group $-CH_2.CO-$ are reduced by heating with phosphorus

tribromide to unsaturated compounds containing the group —CH : CH—. Thus desoxybenzoin, $C_6H_5.CH_2.CO.C_6H_5$, is reduced to stilbene, $C_6H_5.CH : CH.C_6H_5$, and diphenylpyrazolone to diphenylpyrazole. The method is also applicable to some compounds containing the group —NH.CO—, and carbostyril is in part reduced by phosphorus tribromide to quinoline.

The long sought synthesis of camphoric acid has been recently accomplished by Dr. Komppa, of Helsingfors (Finland), and is described in the *Berichte* of December 29, 1903. Two years ago the author described the synthesis of apocamphoric acid, which differs from camphoric acid only in the presence of a hydrogen atom in place of one of the methyl groups. The methyl group cannot be introduced directly into apocamphoric acid, but the diketo-apocamphoric ester can be methylated and yields a diketocamphoric acid which can be indirectly reduced to camphoric acid,



The synthetical acid is optically inactive, but proved to be identical with the known racemic form of camphoric acid. The synthesis includes also the preparation of camphor from its elements, since the conversion of camphoric acid into camphor was accomplished some years ago by Haller. Although the correctness of Bredt's formula for camphor has been fully established by the synthesis of several of its oxidation products, the synthesis of the ketone itself has for some years been one of the most attractive problems in organic chemistry, and its solution completes a not unimportant chapter in the history of chemical progress.

The additions to the Zoological Society's Gardens during the past week include a Raven (*Corvus corax*), British, presented by Mr. George Ogilvie; a Mongoose Lemur (*Lemur mongoz*) from Madagascar, two Sulphury Tyrants (*Pitangus sulphuratus*) from South America, deposited; a Llama (*Lama peruana*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Distribution of the Stars.—No. 5, vol. xlviii., of the Harvard College Observatory *Annals* contains a discussion of the distribution of the stars throughout the whole sky. A special point of the discussion was to determine the relative numbers of the stars situated in the Milky Way and those outside its limits. The number of stars in the galaxy was determined from the charts given in Heis's atlas and the Uranometria Argentina; those without were determined from the Harvard Durchmusterungs. Twenty-three tables included in the paper set out the various results in detail, but the following are among the chief facts determined.

The number of stars in a given area of the Milky Way is about twice as great as in an equal area of any other region, and this ratio does not increase for faint stars down to the twelfth magnitude; the proportion of stars of any given magnitude is the same in the Milky Way as in the other regions. The Milky Way covers about one-third of the sky, and contains about half of the stars. There is no evidence of any limit to the faintness of the stars, although the proportionate increase becomes less for each successive magnitude. There are about 10,000 stars of magnitude 6·6 or brighter, 100,000 of magnitude 8·7, 1,000,000 of magnitude 11·0, and 2,000,000 of magnitude 11·9. Although uncertain, it is suggested that there are about eighteen millions of stars visible in a telescope of 15 inches aperture, *i.e.* down to about the fifteenth magnitude.

The distribution of various spectral types has also been considered, and the most striking fact is the preponderance of stars of class "A" and "K" (Harvard), which in a general classification may be taken as typical spectra, the others being simply modifications of these. Many other extremely interesting facts have been elicited during the discussion, but they are too numerous to mention here.

Report of the Windsor, N.S.W., Observatory.—Mr. Tebbutt's report of the work performed at this observatory (Windsor, N.S.W.) during 1902 deals chiefly with meridian observations for the determination of local time and star places. Most of the extra-meridian work mentioned has already been published in the *Astronomische Nachrichten*, and includes observations of minor planets (for positions) and Perrine's comet (1902 *b*). The reduced measures of fifty-four of the double-stars given in Innes's "Reference Catalogue," involving 1757 settings for position angle and 1503 for distance, have been communicated to the Royal Astronomical Society. The local meteorological results, given in the report, include monthly returns of temperature and rainfall observations, and show that the number of inches, recorded by a rain-gauge placed about 7 feet above the ground, is less than for any year since 1863, being, in fact, about 14·5 inches below the average for forty years. A number of comparisons of the temperatures recorded by two thermometers, one in a Greenwich the other in a Stevenson screen, showed that an excess amounting to between one and two degrees was registered by the former.

A French-Chinese Calendar.—The "Calendrier Annuaire" for 1904, compiled at the Li-Ka-Wei Observatory, and published at the price of one dollar by the Catholic Mission at Shanghai, is an interesting calendar containing many astronomical, meteorological and physical tables.

The calendar is printed in French, but all proper names and technical terms are also given in Chinese characters and words. Among the more important matters dealt with there occur a lucid explanation of the Chinese calendar, many astronomical tables and explanatory notes, tables for the conversion of Chinese and Japanese standards into European equivalents, facts regarding the population, area and political relations of China, and a number of tables and curves relating to the meteorology of the Chinese Empire.

A Bright Bolide.—A remarkable bolide was observed by Mr. W. E. Rolston at Fulham at about 8h. 27m. p.m. on January 9. It appeared at a point situated at about $\alpha = 102°$, $\delta = +18°$, and slowly travelled towards the constellation Cancer, leaving a bright, scintillating, reddish trail. When near to the point $\alpha = 112°$, $\delta = +18°$ (approx.) the head slowly swelled out into a bulbous shape having a yellowish-red hue, became considerably brighter than Jupiter, and then suddenly disappeared. The duration of the complete phenomenon was about five or six seconds.

THE PHYSICAL LABORATORY AT LEYDEN.

An account of this laboratory, published in Nature of August 13, 1896 (vol. liv. p. 345), dealt with the inception of the cryogenic department in 1883, and traced its development up to date. It is the purpose of this note to continue the account to the present time, both as regards the more important changes and improvements in the cryogenic department itself, and also in the remaining divisions of the laboratory.

As before, the communications continue to give an almost complete account of the results of the practical work carried out, together with certain more theoretical papers in direct connection with this. Since 1898, the Royal Academy of Amsterdam has published its *Proceedings* in English as well as in Dutch, so that the communications are now corrected reprints of the *Proceedings*. Some idea may be gathered of the increasing output of work when it is noted that in 1896 the current number of the communications was twenty-three, while it has now risen to eighty-eight.

This increasing productivity is mainly due to the much improved appliances, both for manipulation and measurement, which have been developed during the last ten years. Although the original system of three main cycles containing methyl chloride, ethylene and oxygen has been retained, almost every part has been improved and enlarged, so that the ease and rapidity of working are much enhanced. In

addition several auxiliary circulations have been constructed in order to add new ranges of temperature to those already obtainable by the main cycles, or at least to make certain temperatures more practicable. Of these the principal are:—(1) a circulation of strong calcium chloride solution cooled to about $-23°$ C. by methyl chloride, and then heated again to the required constant temperature in a thermostat; (2) a nitrous oxide circulation, also in connection with the methyl chloride, for temperatures about $-90°$ C.; (3) air; (4) nitrogen; and (5) methane in connection with the oxygen cycle. In this way the entire range between $+5°$ and $-210°$ can be covered with but few gaps.

The efficiency of the circulations is now very high, as each step in the cascade only lasts about 20 minutes, so that liquid nitrogen even, which requires four operations, is obtained in 1 hour 20 minutes. For this purpose about 6 kg. methyl chloride, 1·3 kg. ethylene, 2·5 kg. oxygen, and 1·0 kg. nitrogen are required, with the pumps running at about 5, 6, 30, and 6 atmospheres pressure in the respective cycles. In order to obtain this speed of work a new large Burckhardt-Weiss pump, with a capacity of 100 litres per second and capable of evacuating to 2 mm. of mercury, has been introduced before the vacuum cylinder of the Pictet conjugated pump in both methyl chloride and ethylene circulations. In the case when a bath of liquid nitrogen is required, one of the two Brotherhood compressors is put into the oxygen circulation, while the nitrogen is compressed in the modified Cailletet pump mentioned before, after passing through an auxiliary pump, to bring it to about 10 atmospheres pressure.

Two methods are employed for conveying the liquid gas required from the cryogenic room to one of three experimenting rooms. Where many measurements at a reduced temperature are desired, hence necessitating a frequent addition of liquid, methyl chloride, nitrous oxide, and ethylene have been conveyed in a copper tube well wrapped up in wool and paper for a distance of about 10 metres. In other cases the liquid is run into specially mounted vacuum glasses, which are transported to the experimental vessel, into which the liquid is siphoned over. Measurements have been made in this way with all the gases mentioned, in vessels which require the use of litres of liquid.

One of Prof. Onnes's chief objects in founding his cryogenic department was the experimental determination of accurate isothermals of pure elementary gases and their binary mixtures, at temperatures near the critical. Although measurements had been made on methyl chloride, carbon dioxide, and mixtures of these with oxygen or hydrogen, no measurements on the latter gases alone had been attempted until about four years ago. The first necessity was a standard open mercury manometer for the very accurate determination of pressures up to 64 atmospheres. Since this has been available, measurements have been made on hydrogen, oxygen, and nitrogen at ordinary and at low temperatures to an accuracy unattained before in such work. At the same time very careful comparisons have been made between the expansion coefficients, at constant volume, of the same gases at low temperatures. In order that these measurements should be possible, it was also necessary to develop the system for the determination of temperature to the accuracy required. For this purpose use has been made of constant volume hydrogen thermometers and of specially prepared and calibrated platinum resistances or thermoelements.

For the most recent measurements it has been found advisable to employ, at the same time, both a temperature indicator and a temperature measurer. The measuring instrument must be sensitive enough for the accuracy required, but the indicator must be set to a higher order. A combination of a platinum resistance, wound upon glass and surrounding the experimental tube, with a thermoelement has usually been employed.

The temperature of an evaporating liquid varies both from the want of homogeneity of the substance and of constancy in the pressure. By suitable adjustment of the pressure, it is possible to make these variations compensate one another, with the result that a nearly constant temperature is obtained. In the thermoelectric circuit variations of 0·01 degree can be immediately seen and corrected by a suitable small change of pressure. Variations due to the pumping machinery and other similar causes are corrected at once from the indications of an oil manometer. In addition, continual stirring by a small motor allows temperatures down to $-210°$ C. to be obtained, which remain constant and uniform to 0·01 degree for an hour in baths 15 cm. in depth.

Preparations are now being made, by the addition of new pumps and other apparatus, for the installation, on the same principles, of a hydrogen cryostate, which will allow of the extension of the range of constant temperatures to the boiling point of hydrogen under reduced pressure.

Since only minor technical difficulties are to be expected, it is probable that this cycle will be completed in a few years' time.

During the past decade several other important investigations have been made. Of these the best known is certainly the discovery and measurement by Dr. Zeeman of the effect which goes by his name. This was largely due to a set of careful experiments and measurements on kindred optical questions, and was tried several times without success. Immediately it was noticed Prof. Lorentz was able to supply the elementary theory, which has subsequently only been elaborated. The discovery thus belongs peculiarly to Leyden, while the partnership was fittingly acknowledged by the joint award of the Nobel prize in 1902.

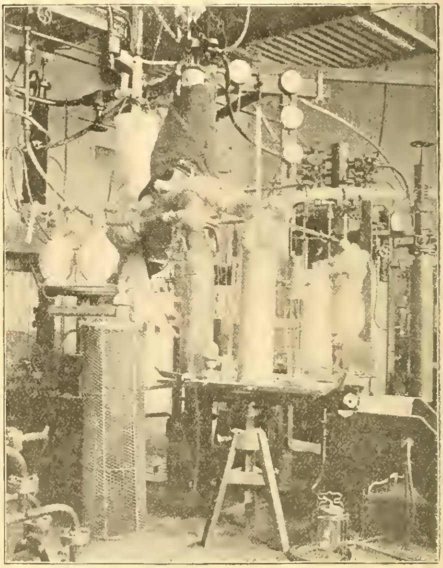


FIG. 1.—The immediate apparatus for the preparation of liquid nitrogen or methane. The liquefied gas is being collected in the metal cylinders in middle of picture. This apparatus stands at the end of the room from which the view shown in 1896 was taken.

What Prof. Onnes considers as to some extent a new method of thermodynamical research has been recently developed by him. It consists in making large accurate models of both the Gibbs (ϵ, η, v) and van der Waals (ψ, v, x) surfaces. By means of these many problems can be treated with comparative ease, which otherwise would either be impossible or would involve very lengthy calculations.

The following list of the principal researches from the beginning of the communications will show clearly the range of work covered.

To make it a continuation of that in the former note the same numbers have been retained :—

(1) Cryogenic department. Pumps, cycles, experimental apparatus, &c. (Nos. 14, 23, 51, 54, 85).

(2) Investigations regarding condensation of mixtures (Kuenen, Nos. 4, 7, 8, 11, 13, 16, 17; Hartman, Nos. 43, 56, 64, Supplement 3; Verschaffelt, Nos. 45, 47, 55, 65; Keesom, 88).

(3) Measurements on capillarity (de Vries, No. 6; Verschaffelt, Nos. 18, 28, 32; van Eldik, No. 39).

(4) Measurements on viscosity of methyl chloride (Stoel and Haas, Nos. 2, 12).

(5) Experiments on Kerr's magneto-optical phenomenon (Sissingh, Wind and Zeeman, Nos. 1, 3, 5, 8, 9, 10, 15, 20); on the influence of magnetism on light (Zeeman, Nos. 29 33. 36).

(6) Measurements of the Hall phenomenon in bismuth (Lebret, Nos. 15, 19; van Everdingen, Supplement 2, 61, 63. 72).

(7) On Hertz waves in water and electrolytes (Zeeman, Nos. 21, 22, and with Cohn, No. 30).

(8) The dispersion of the magnetic rotation in gases and liquid gases (Siertsema, Supplement 1, Nos. 62, 73, 76, 80, 82).

(9) The accurate measurement of very low temperatures (Kamerlingh Onnes, Nos. 27, 44, 50, and Boudin, No. 60, and Heuse, No. 87; Meilink, No. 77).

(10) Dielectric constants of liquid gases (Hasenoehrl, No. 52).

(11) Accurate isothermals and critical constants of diatomic gases (Schalkwyk, Nos. 67, 70; Kamerlingh Onnes and Hyndman, Nos. 69, 78, 84).

(12) Contributions to the knowledge of van der Waals's ψ surface (Kamerlingh Onnes, Nos. 59*a*, 66, and Reinganum, No. 59*b*, and Happel, No. 86; Keesom, Nos. 75, 79; Verschaffelt, No. 81).

(13) The expression of equations of state by means of series (Kamerlingh Onnes, Nos. 72, 74).

In addition, measurements have been made at low temperatures, and will be published shortly, relating to the pressure coefficient of oxygen and nitrogen at both ordinary and high pressures, and also to the critical phenomena and constants of oxygen.

At the present time the electrical installations of the laboratory are being largely increased. There are already three dynamos which can give a current of 200 amperes at 120 volts, and two motors will be ready shortly to drive some of the pumps and other apparatus.

The possibility of making and fitting the highly specialised and intricate apparatus required for some of these measurements is largely aided by the circumstance that the laboratory is combined with a technical school for instrument making and certain branches of electrical technology. About twenty apprentices are at present passing through the wood, metal, and glass workshops, each of which is controlled by a skilled workman. In this way the construction and repair of apparatus, and the help required for complicated experiments, can be obtained in a most satisfactory manner. This unique combination of research laboratory and technical school is well worth a visit from physicists touring in Holland, who will receive a friendly welcome from Prof. Onnes.

H. H. F. HYNDMAN.

AUSTRIAN GEOLOGICAL SURVEY.

SOME important publications of the Austrian Geological Survey have reached us, namely, the first part of the twentieth volume of the *Abhandlungen der k.k. Geologischen Reichsanstalt*, Vienna (1903), the second, third and fourth parts of the fifty-second volume and the first part of the fifty-third volume of the *Jahrbuch* (1902–1903).

The first of these works is a valuable memoir by Ernst Kittl, on the Cephalopoda of the Upper Werfen beds of Muć, in Dalmatia, and other localities, and comprises seventy-seven pages and eleven plates. As indicated by the title, the greater part of the material described in this memoir was obtained from the locality discovered in 1862 at Muć (or Much), in northern Dalmatia, but some of the specimens are from other areas, including certain Alpine localities. Some account is given of the various places where similar strata have been met with, and numerous references are made to the writings of other workers. The description of the various genera and species constitutes the bulk of the work. All the forms noticed are included in two families :—(1) the Ceratitidæ, with the genera Dinarites, Stacheites, Ceratites, and Tirolites; and (2) the family Pinacoceratidæ, with the genera Kymatites, Meekoceras, and Dalmatites. Of these genera Stacheites alone is new to science, but certain subgenera and thirty-four species are described and named for the first time.

In conclusion, the author directs special attention to the importance of the few precursors of the Muschelkalk Cephalopoda, such as Dalmatites, Ceratites, and some nearly allied forms, which are now for the first time known to occur in the Werfen beds.

A comparison with the Permian and Carboniferous fauna of Silesia, Russia, and India shows the comparative poverty of the Werfen beds, and the author points out that the scanty fauna goes "hand in hand" with the small amount of calcareous matter in the deposit.

The second part of the *Jahrbuch* indicated above contains several interesting papers on various subjects, each being illustrated by plates or text figures. Dr. Karl Hinterlechner describes the petrographical characters of some rocks from the Cambrians of western Bohemia. The "Erzberg" in Hüttenberg, Carinthia, is described by Bruno Baumgärtel; Dr. Rudolf Zuber gives us some new studies in the Carpathians; while Hermann Bock supplies an account of the physical structure of the neighbourhood of Brünn. Then follow three palæontological papers :—Rich. Joh. Schubert, on some bivalves from the Istro-Dalmatian "Rudistenkalkes"; Vincenz Hilber, on some fossils from the Gosau beds of Kainach and Söding, in the northern parts of Voitsberg—in this paper one new species is described under the name of *Hippurites Styriacus*; Adalbert Liebus and Rich. Joh. Schubert describe the Foraminifera from the Carpathian Inoceramus beds of Gbellan, in Hungary, seven new species and four new varieties being named. The concluding paper, and certainly not the least important, is by Dr. H. Graf Keyserling, and is entitled "Geologico-petrographical Studies in the Region of the Melaphyre and Augiteporphyry of the Southern Tyrol." This is a detailed communication of some forty pages, which will doubtless be carefully studied by all interested in this particular subject.

The third part is devoted to a detailed account of the localities and horizons yielding useful minerals in the so-called Archaic and Devonian island of Westmähren, by Franz Kretschmer, mining engineer at Steinberg. This memoir of 142 pages deals very fully with the geological and physical conditions under which the graphite, lead, iron ores, &c., are found, and it is illustrated by a geologically coloured map, with sections and plans.

The fourth part of this volume is a memoir by A. Bettner on the Brachiopoda and Lamellibranchiata from the Trias of Bosnia, Dalmatia, and Venetia, occupying 149 pages, and illustrated by ten lithographic plates and seventeen zincographs in the text. The greater part of this work deals with fossils of Middle Trias or Muschelkalk age, derived from several localities, but perhaps a greater interest will be attached to the last twenty pages, dealing with the Upper Trias or Keuper forms from two localities in Bosnia. The whole memoir is a detailed description of species, and, as might be expected from their age and the little known localities from which they are derived, many of them prove to be new, but one cannot but be surprised to find that of some two hundred forms here described one hundred require new names. The plates accompanying this work are clearly drawn, but it is to be regretted that the figures are so crowded. All who have worked with such plates know how troublesome this is; one's eyes become dazed when trying to concentrate upon any particular figure. No doubt this memoir, like the one above noticed on the Werfen Cephalopoda, will become a classic in Triassic literature.

Part i. of vol. liii. contains several papers; the first of these, by R. Hoernes, on the ontogeny and phylogeny of

the Cephalopoda, deals with the initial chamber of the Nautiloidea, especially in the genus Orthoceras. Dr. Richard Johann Schubert and Dr. Lukas Waagen give an account of the Lower Silurian phyllopod genus Ribeiria, and establish a new genus, Ribeirella, for the species *R. Sharpei*, Barr. The remains of a male sheep's skull (*Ovis Mannhardi*) from the neighbourhood of Eggenburg are described by F. Toula, and carefully compared with recent and fossil forms; the paper is illustrated by a plate showing three views reproduced by photography and by three text figures. Dr. W. Hammer gives an account of the minute structure of porphyrite and diorite rocks from Ultenthal, giving six excellent photographic reproductions of microscopic sections. Dr. O. Able, in a memoir of some 50 pages, treats of the Tertiary marls and sandstones of the Tulln basin from both stratigraphical and physical standpoints, and comes to the conclusion that they begin with the Lower Oligocene and continue in unbroken series to the base of the Oncophora sands (Middle Miocene). Four sections across the valley are given to show the folding of the beds. Dr. Karl Alphons Penecke, in a paper of a dozen pages, describes a number of Upper Devonian corals obtained by Dr. Franz Scaffer from Hadschin, Antitaurus, during his journey in Asia Minor. Three new species are named. These corals are finely reproduced by photography on four double plates. In the last paper of this part Dr. W. Petrascheck describes some Inocerami from the Chalk of Bohemia and Saxony, giving the names *Ino. hercynieus* and *Ino. crassus* to two new species. This troublesome genus needs a thorough revision, and it is hoped that ere long someone will be found to undertake this useful piece of work, at least for the Cretaceous species.

ATMOSPHERIC ABSORPTION AND EMISSION OF THE EXTREME ULTRA-VIOLET RADIATIONS.

No. 1413 of the "Smithsonian Contributions to Knowledge" is devoted to a paper by Dr. Victor Schumann, of Leipzig, in which he minutely describes the apparatus used and the results obtained by him in spectroscopically determining the absorption and emission of air and its constituents for light of wave-lengths between 250 $\mu\mu$ and 100 $\mu\mu$. He obtained the photographic spectra of N, O, CO_2, CO, aqueous vapour and hydrogen by means of an ingeniously constructed spectroscope, from which he could exhaust all the gas except that on which he was experimenting, and this he introduced, in layers of definite thicknesses, after repeated purification. All the optical parts of the apparatus were made of white fluorspar, which is the most transparent substance, for these extreme ultra-violet rays, yet known.

Dr. Schumann found that nitrogen is very transparent even beyond 162 $\mu\mu$, but absorbs particular wave-lengths very energetically; the emission spectrum extends beyond 162 $\mu\mu$. Oxygen absorbs the radiations near to 185 $\mu\mu$ in a series of clearly resolved groups of lines, fourteen in number, complete absorption taking place beyond the most refrangible group of the series. This absorption is believed to be the cause of the atmosphere's opacity for radiations more refrangible than 185 $\mu\mu$. The absorption spectrum of CO_2 is similar in appearance to that of oxygen, but extends to much shorter wave-lengths; the persistent presence of bands due to carbon monoxide—which is one of the greatest difficulties Dr. Schumann has had to contend with in all his experiments, because their photographic action is exceedingly energetic and they extend far beyond 162 $\mu\mu$—has prevented the exact determination of the more refrangible limit of the CO_2 spectrum, which is exceedingly rich in lines. Carbon monoxide absorbs the more refrangible rays a little less than CO_2. The results of the experiments on the spectrum of aqueous vapour are rather uncertain owing to the formation of dew, but it chiefly consists of the hydrogen spectrum, the strong oxygen maximum at 185 $\mu\mu$, and a number of other lines the origin of which is at present unknown. The results, however, lead to the conclusion that a regular dissociation of the water vapour, accompanied by a simultaneous recombination, takes place. The results obtained with hydrogen are exceedingly interesting, and are discussed *in extenso* by Dr. Schumann. They show that hydrogen is intensely transparent, but the limit of transparency is not yet definitely determined. Twenty-fold enlargements of the hydrogen spectrum—having a total length of 1·4 metres—are reproduced in the paper, and show about 1500 lines between 185 $\mu\mu$ and 127 $\mu\mu$. Dr. Schumann states, however, that this latter value is rather uncertain, and is probably not the inferior limit of the true hydrogen spectrum as photographed by him. He also believes that between 185 $\mu\mu$ and 369·9 $\mu\mu$ the hydrogen spectrum is continuous.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Mr. S. A. F. White, demonstrator in natural philosophy in King's College, London, since 1895, has been appointed professor of mathematics in succession to Prof. Hudson.

Dr. W. A. Osborne has been appointed to the professorship of physiology and histology in the University of Melbourne in succession to Dr. C. J. Martin, F.R.S., now director of the Lister Institute.

The Technical Education Board of the London County Council has arranged for two courses of free lectures for teachers to be given at the Horniman Museum, London Road, Forest Hill, S.E., on Saturday mornings from January 23 to May 26. Prof. Geddes will lecture on the natural history of plants, and a course of lectures on the natural history of man will be given by Prof. Alfred C. Haddon, F.R.S.

The annual meeting of the Association of Public School Science Masters will be held at Westminster School on Saturday, January 16, beginning at 1.45 p.m. Prof. W. A. Tilden, F.R.S., president of the Association, will be in the chair. Mr. R. E. Thwaites will read a paper on the possibility of fusing the mathematical and science teaching of public schools; and a discussion on science in the certificate examination will be opened by Mr. W. A. Shenstone, F.R.S., and Mr. M. D. Hill, who will deal with the chemical and biological parts of the examination respectively. Mr. O. H. Latter will read a paper on nature-study.

The eleventh annual general meeting of the Association of Technical Institutions will be held on Friday, January 29, at the Leathersellers' Hall, London, E.C., the president, Sir John Wolfe Barry, K.C.B., F.R.S., in the chair. Sir John E. Gorst, K.C., M.P., has consented to be nominated president of the association for the year 1904. Among other subjects to be brought before the meeting are:—Report as to the constitution of the advisory committee for the leather trades industries, in connection with the City and Guilds of London Institute, Prof. Wertheimer; the differences between the curricula and methods of staffing in British and American higher technical institutions, Dr. Walmsley; the consultative committee of the Board of Education and teachers' registration council, Principal Wells and Dr. Sumpner; and leaving certificates for secondary schools, Prof. Wertheimer and Principal Gannon.

An interesting essay by Dr. Walther Schoenichen on "The Evolution Theory in Schools" (Die Abstammungslehre im Unterrichte der Schule) has been published by the firm of Teubner (Leipzig and Berlin). The author shows that school instruction in botany and zoology has already passed through several phases—encyclopædic, systematic, analytic, and ethological—and maintains that the time has come for making it frankly evolutionary. This is necessary for scientific reasons and desirable for educational reasons, and, according to the author, it is also quite feasible. He argues that it will be useful ethically and will not endanger religion. The essay is wise and temperate, and many of the practical hints are very suggestive, *e.g.* the diagrams contrasting the multiplication of the hare and the elephant, the evolution of the kohl-rabi cabbage, and the origin of light-coloured from dark-coloured mice by selection.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 19, 1903.—"On the Physiological Action and Antidotes of Colubrine and Viperine Snake Venoms." By Dr. Leonard **Rogers.** Communicated by Dr. A. D. Waller, F.R.S.

The actions of various venoms have been studied by means of respiratory and circulatory tracings, &c. Firstly, the poisonous colubrine Indian snakes were dealt with. The *Loia bungarus* or hamadryad, the largest poisonous snake in India, was found to cause death by paralysing the respiratory centre, quickly followed by the motor end plates of the phrenic nerves, just as in the case of cobra. The *Bungarus coeruleus,* or common krait, also produced the same effect, only the end plate action was less marked. The *Bungarus fasciatus,* or banded krait, produced similar symptoms to the above in small doses, with the addition of marked circulatory failure, and in large doses also intravascular clotting like the vipers, and its venom was found to be a mixture of colubrine and viperine elements. The hæmolytic action of the above three venoms was much less marked than in the case of cobra venom, and has no lethal importance. The physiological action of the above and of the sea snakes having been found similar to that of cobra venom (with the exception of the added viperine element in the *Bungarus fasciatus*), Calmette antivenin was tested against them all, and found to be effective in varying degrees in each with the exception of the *Bungarus fasciatus*, in the case of which the colubrine element alone is neutralised, but the viperine one proves fatal. The serum is not, however, strong enough to be of the greatest value.

Secondly, the two true vipers, the *Daboia russellii* and the African puff adder, and two pit vipers, the *Crotalus horridus* and the *Trimenurus anamallensis*, were examined, and it was found that the one essential action common to all four was a paralysis of the central vasomotor centre producing a marked fall of blood pressure, followed sooner or later by secondary respiratory failure, but counteracted in a marked degree for a time by adrenal extract. In the case of the true vipers, large doses produce intravascular clotting, but by giving small preliminary doses, fatal vasomotor paralysis can readily be induced without any clotting whatever, while the venom of the rattlesnake readily produces the same effect without clotting in a single large dose, and also marked hæmorrhages, which are not caused by the Daboia.

December 3, 1903.—"On the Fructification of *Neuropteris heterophylla*, Brongniart." By Robert **Kidston,** F.R.S.

Royal Microscopical Society, December 16, 1903.—Dr. Hy. Woodward, F.R.S., president, in the chair.—Mr. F. W. Watson **Baker** exhibited under microscopes a series of slides, sixteen in number, illustrating the development of an ascidian from the fertilisation of the ovum to the larval stage.—Dr. G. J. **Hinde** read a paper on the structure and affinities of the genus Porosphæra.

MANCHESTER.

Literary and Philosophical Society, December 1, 1903.—Prof. W. Boyd Dawkins, president, in the chair.—The president directed the attention of the meeting to the fact that, although the rainfall during the last six months had been unusually heavy, the water in the deep springs had not increased proportionally, but was still below the average quantity for the last ten years.—Dr. W. E. **Hoyle** exhibited a model of the mole's nest, prepared by Mr. Lionel E. Adams, who read a paper on the subject before the Society some time ago. The model is in three parts, and shows the construction of a typical nest of the male mole very clearly.—Mr. F. F. **Laidlaw** read a paper entitled "Suggestions for a Revision of the Classification of the Polyclad Turbellaria," in which he considered more especially the acotylean genera, and based his classification of them on the characters of the prostate gland.

December 15, 1903.—Mr. Charles Bailey in the chair.—Prof. E. **Knecht** read a paper on an interesting reaction of copper salts. More than fifty years ago, Ebelmen had, in describing the properties of titanium trichloride, alluded to the property which this substance possesses of precipitating gold, silver, and mercury from their salts. The author showed that by using an excess of the trichloride, metallic copper could be precipitated from solutions of its salts, but pointed out that the reaction was a reversible one, and was consequently not complete. With titanous sulphate, however, the reaction with copper salts was complete, the copper appearing as an extremely fine metallic looking precipitate even in very dilute solutions (1 pt. in 1,000,000).—The electrolytic method for the detection and approximate estimation of minute quantities of arsenic in malt, beer, and food stuffs, by Mr. W. **Thomson.** An exhaustive series of tests has been made with the electrolytic apparatus devised by the committee appointed by the Commissioners of Inland Revenue in comparison with those obtained by the Marsh-Berzelius apparatus. From the results obtained the author lays stress on the importance of destroying the organic matter in beer, malt, &c., before introducing into the apparatus, and also puts forward the electrolytic method with zinc kathode as the most satisfactory for the estimation of minute quantities of arsenic.

DUBLIN.

Royal Irish Academy, Dec. 14, 1903.—Prof. R. Atkinson, president, in the chair.—Some new relations in the theory of screws, by Prof. C. J. **Joly.** Let A, B, C be any three points on the axes of any three screws, (1), (2) and (3) respectively, of a given three-system. Let B_1C_1 be the projection of BC on the axis of (1). Let (23) be the angle between the axes of the screws (2) and (3), and let sin (123) be the sine of the solid angle determined by the three axes. Then

$$\frac{B_1C_1 \cos (23) + C_2A_2 \cos (31) + A_3B_3 \cos (12)}{\sin (123)} + p_1 + p_2 + p_3 = a + b + c,$$

where p_1, p_2, p_3 are the pitches of the three screws, and a, b, c the pitches of the principal screws of the system. The author derived his results by the method of quaternion arrays, and showed that many relations similar to that given above may be deduced for screw-systems of any order.—Mr. John **Fraser** reduced the equation of a quartic surface possessing a nodal conic to the sum of squares of the five Jacobian quadrics of the systems of quadrics which pass through the conic, and which have double contact with the quartic surface. He gave explicitly the equations of the quadrics, and showed that the same method was applicable in the case of binodal quartic curves.

PARIS.

Academy of Sciences, January 4.—M. Mascart in the chair.—Researches on the emission of water vapour by plants and on their spontaneous desiccation: M. **Berthelot.** The roots and leaves of the plant investigated were first air-dried separately at the ordinary temperature, the temperature and hygrometric state varying during the experiment. After about eight days equilibrium was established, when the plants were further dried at 110°. A further loss of water was measured.—Proof of an experimental law given by M. Parenty on the flow of gases through orifices: J. **Boussinesq.**—The notion of work applied to the magnetisation of crystals: Pierre **Weiss.**—On osmosis: A. **Guillemin.** Adopting the theory of Halley, and the idea of the existence of a tension of expansibility, increasing with the depth below the free surface, the law of osmotic equilibrium takes the form that osmotic equilibrium exists when the tension of expansibility is the same on each side of the semi-permeable wall.—On the absolute value of the magnetic elements on January 1: Th. **Moureaux.** The absolute values and secular variation are given for the Observatory of Val-Joyeux, latitude 48° 49′ 16″ N., longitude 0° 19′ 23″ W.—On the stability of the direction of magnetisation in some volcanic rocks: Pierre **David.** It has been previously shown that some volcanic rocks possess a permanent magnetisation, which is probably that of the direction of the earth's field at the time when the rock solidified. This view has been confirmed by the examination of pieces of volcanic rocks taken from buildings dating from the Roman period. The inclination of all the pieces examined is identical, but the declination is variable.—On the decrease of temperature with height in the neighbourhood of Paris,

from five years' observations: Teisserenc **de Bort.** A summary of results obtained from experiments with captive balloons at heights varying from 500 to 14,000 metres.—Differential characters of the physiological radiations according as their origin is muscular or nervous: Augustin **Charpentier.** The rays emitted by muscle appear to be identical with the *n*-rays of Blondlot, but those emitted by nerves differ from these in that they are partially arrested by aluminium.—On the phosphoric esters of glycerin: P. **Carré.** The retrogradation and coagulation of starch: L. **Maquenne, A. Fernbach** and J. **Wolff.**—The use of sodium sulphide as an indicator in the estimation of glucose by Fehling's solution: L. **Beulaygue.** Very exact results can be obtained in sugar titrations by the use of spots of sodium sulphide on filter paper as an indicator.—The ablation of the parathyroids in birds: MM. **Doyon** and A. **Jouty.**—The selection of small differences which present the characters with continuous variations: Georges **Coutagne.**—On the double secreting apparatus of Dipteryx: Édouard **Heckel** and H. Jacob **de Cordemoy.**—On polymorphic transformations: M. **Wallerant.**—On the geology of the Alps: Émile **Haug.**—Contribution to the knowledge of the Lutecian formations of Senegal: Stanislas **Meunier.** The material collected by M. Friry confirms the view that there was a large Eocene sea in Africa, and also tends to show that there was direct marine communication between Senegal and Egypt.—On a substitute for ligatures in surgery: M. **Wassilieff.**

DIARY OF SOCIETIES.

THURSDAY, JANUARY 14.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—The City and South London Railway; Working Results of the Three Wire System applied to Traction, &c.: P. V. McMahon. (Adjourned discussion.)—On the Magnetic Dispersion in Induction Motors, and its Influence on the Design of these Machines: Dr. Hans Behn-Eschenburg.

ROYAL INSTITUTION, at 5.—The Flora of the Ocean: G. R. M. Murray, F.R.S.

MATHEMATICAL SOCIETY, at 5.30.—On Various Systems of Piling: Prof. J. D. Everett.—The Solution of Partial Differential Equations by Means of Definite Integrals:

$$\frac{\partial^2 V}{\partial x_1^2}+\frac{\partial^2 V}{\partial x_2^2}+\ldots+\frac{\partial^2 V}{\partial x_n^2}=0:$$

H. Bateman.—On the Notion of Lines of Curvature in the Theory of Surfaces: Dr. G. Prasad. On Groups of Order $p^\alpha q^\beta$: Prof. W. Burnside.—Electric Radiation from Conductors: H. M. Macdonald.—Open Sets of Points and the Theory of Content: Dr. W. H. Young.

SOCIETY OF ARTS, at 4.30.—The Presidency of Bombay: Sir William Lee-Warner, K.C.S.I.

FRIDAY, JANUARY 15.

ROYAL INSTITUTION, at 9.—Shadows: Lord Rayleigh.

INSTITUTION OF MECHANICAL ENGINEERS, at 8.—Sixth Report to the Alloys Research Committee on the Tempering of Steel: the late Sir William C. Roberts-Austen, K.C.B., F.R.S., and Prof. William Gowland.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Pumping and Disposal of Sewage at York: A. D. Creer.

PUBLIC SCHOOL SCIENCE MASTERS' ASSOCIATION, at 1.45.—The Possibility of Fusing the Mathematical and Science Teaching of Public Schools: R. E. Thwaites.—Science in the Certificate Examination: W. A. Shenstone, F.R.S., and M. D. Hill. Nature Study: O. H. Latter.

SATURDAY, JANUARY 16.

ROYAL INSTITUTION, at 3.—British Folk Song: J. A. F. Maitland.

TUESDAY, JANUARY 19.

ROYAL INSTITUTION, at 5.—The Development of Animals: Prof. L. C. Miall, F.R.S.

ROYAL STATISTICAL SOCIETY, at 5.

ZOOLOGICAL SOCIETY, at 8.30.—A Monograph of the Coleoptera of the Genus Hipporhinus: Guy A. K. Marshall.—On Proposed Additions to the Accepted Systematic Characters of Certain Mammals: Dr. Walter Kidd.—Some Observations on the Skull of the Giraffe: Dr. W. G. Ridewood.

SOCIETY OF ARTS, at 8.—Celtic Ornament: George Coffey.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Discussion of Paper on the Electrical Re-construction of the South London Tramways on the Conduit System: A. Millar.—To be followed by: The Sanding-up of Tidal Harbours: A. E. Carey.

WEDNESDAY, JANUARY 20.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—Presidential Address, The Present State of Ocean Meteorology: Captain D. Wilson-Barker.

ROYAL MICROSCOPICAL SOCIETY, at 8.—Presidential Address, On the Evolution of Vertebrate Animals in Time: Dr. H. Woodward.

GEOLOGICAL SOCIETY, at 8.—On the Jaws of Ptychodus from the Chalk: Dr. A. Smith Woodward, F.R.S.—On the Igneous Rocks of Spring Cove, near Weston-super-Mare: W. S. Boulton.

CHEMICAL SOCIETY, at 5.30.—Optically Active Asymmetric Nitrogen Compounds *d*- and *l*-phenylmethylethylbenzylammonium Salts: H. O. Jones.—The Chemical Reactions of Nickel Carbonyl, Part I., Reactions with the Halogens, &c.: J. Dewar and H. O. Jones.—The Chemical Reactions of Nickel Carbonyl, Part II., Reaction with Aromatic Hydrocarbons in Presence of Aluminium Chloride. Synthesis of Aldehydes and Anthracene Derivatives: J. Dewar and H. O. Jones.—A Microscopical Method of Determining Molecular Weights: G. Barger.—*o*-Nitrobenzoylacetic Acid: E. R. Needham and W. H. Perkin, jun.—The *cis*- and *trans*-Modifications of $\alpha\alpha\gamma$-Trimethylglutaconic Acid: W. H. Perkin, jun., and Miss A. E. Smith.—The Influence of Nuclear Substitution on the Rate of Oxidation of the Side-chain, I., Oxidation of the Mono- and Di-chlorotoluenes: J. B. Cohen and J. Miller. (1) A Simple Thermostat for Use in Connection with the Refractometric Examination of Oils and Fats. (2) The Interdependence of the Physical and Chemical Criteria in the Analysis of Butter-fat: T. E. Thorpe.—The Condensation of Furfuraldehyde with Sodium Succinate: A. W. Titherley and J. F. Spencer.

ENTOMOLOGICAL SOCIETY, at 8.—Annual Meeting.—The President, Prof. E. B. Poulton, F.R.S., will deliver an Address.

SOCIETY OF ARTS, at 8.—Organ Design: Thomas Casson.

THURSDAY, JANUARY 21.

ROYAL INSTITUTION, at 5.—The Flora of the Ocean: G. R. M. Murray, F.R.S.

LINNEAN SOCIETY, at 8.—An Account of a Plankton Expedition to the Bay of Biscay in H.M.S. *Research* in 1900: Dr. H. G. Fowler.—The Crustacea obtained by Dr. G. H. Fowler in the Biscayan Plankton: Rev. T. R. R. Stebbing, F.R.S.

FRIDAY, JANUARY 22.

ROYAL INSTITUTION, at 9.—Spectroscopic Studies of Astrophysical Problems at Stonyhurst College Observatory: Rev. Walter Sidgreaves, S.J.

PHYSICAL SOCIETY, at 5.—The Photographic Action of Radium Rays: S. Skinner.—Astigmatic Aberration: W. Bennett.—Some New Cases of Interference and Diffraction: Prof. R. W. Wood.—Exhibition of Instruments by Messrs. Crompton and Co.

SATURDAY, JANUARY 23.

ROYAL INSTITUTION, at 3.—British Folk Song: J. A. F. Maitland.

MATHEMATICAL ASSOCIATION, at 2.—Annual Meeting.—Models of Regular and Semi-regular Solids, including the four "polyèdres étoilés" of Poinsot, exhibited by Mr. E. M. Langley.—An Account of a Recent Discussion on the Possibility of Fusion of the Teaching of Mathematics and Science: C. S. Jackson.—A Geometrical Note: J. C. Palmer.—Advanced School Courses of Mathematics: C. A. Rumsey.

CONTENTS.

THURSDAY, JANUARY 21, 1904.

AN EVOLUTIONARY STUDY OF EUROPEAN POLITY.

The Development of European Polity. By Henry Sidgwick. Pp. xxvi + 454. (London: Macmillan and Co., Ltd.; New York: the Macmillan Company, 1903.) Price 10*s.* net.

HENRY SIDGWICK'S exposition of the theory of politics was published in two editions in his lifetime, as is well known to all English students of the subject. These posthumous lectures are the historical complement, "an evolutionary study of the development of polity within the historic period in Europe," as Mrs. Sidgwick says in her preface. The author conceived, as the final part of the work, a comparative study of living modern constitutions, founded so far as possible on personal observation. He did not live, unhappily, to carry out any substantial portion of that design. Everyone who knew Sidgwick or was acquainted with his work would expect his account of any period or aspect of European history to be sound and careful, notwithstanding that he was not a professed historian. Everyone who knows anything of the difference between finished and not quite finished work is aware of the difficulties that commonly attend the posthumous publication of an author's materials, even if he has not had the experience of being charged with such a production himself. General observations of this kind prepare the way, in many cases, for an appreciation more or less apologetic in tone.

On this occasion there is no question of apologies. We are not surprised that Mrs. Sidgwick's intimate knowledge and sympathy have given us a book in which not only there is no jarring contrast between the author's and the editor's hand, but the difference is barely discernible. We do confess to a little surprise at the comprehensive grasp of the matter, and the almost invariable sureness of judgment, disclosed in these lectures. Historical students who have no taste for philosophy (a mistaken frame of mind in our opinion, but common) may well be tempted to regret that Henry Sidgwick was not a historian altogether. We do not know of any book in English that covers the same ground as this; among those which intersect its lines it would be possible to find more wealth of learning and greater brilliance of style, but very hard to find so safe and impartial a guide.

As the topics dealt with range from the patriarchal family to modern cabinet government, and the treatment—even without the author's last hand—is by no means diffuse, it would be idle to attempt a summary. We may note, however, that the book is provided, as every book of its kind should be, with an excellent analytical table of contents as well as an index. In the earlier part there is a refreshing freedom from mere antiquarianism. Such a quietly humorous note as this on the Homeric banquets:—"Political dinners are very primitive institutions," is more effective than many solemn paragraphs to make the learner understand that even archaic history is concerned with real human nature.

The short chapter on the patriarchal theory partly follows and partly criticises Maine, and leads to the conclusion that

> "there is no reason to regard the father's power, in the patriarchal family, as the original type of political power; but doubtless the firm establishment of the patriarchal type of family contributed importantly to the stability and strength of tribal headship."

Indeed, Maine's own perfectly just view that the units of archaic society are not individuals but families requires us to ask, in the first instance, not how kingship, but how the primacy of one family or clan in the tribe is accounted for. Sidgwick's task was somewhat lightened here by the clear consciousness that he was trying to account only for European and not (for example) Mongol or Polynesian institutions. If Maine himself had more plainly disclaimed any intention of dogmatising on anthropology at large, some not very profitable controversy might have been spared.

A word of special criticism on Maine occurs in a later chapter:—

> "I cannot agree with Maine that codes [in early Greek and Roman history] generally included no new law."

This, no doubt, is sound in itself, but we cannot find that Maine really committed himself to any such statement, though he dwells mainly on the consolidating function of ancient codes. Farther on we have a more substantial amendment. Sidgwick declines to conceive the Roman *jus gentium* as formed by a process of deliberate selection from the customs of different Italian (or Mediterranean) communities.

> "It is clear," he says, "that the development of the kind of law afterwards known as *jus gentium* was entirely due to practical needs; and we may connect it with the development of Roman trade."

It is right to point out that Maine himself, in his later work, did suggest a connection with market law. The present writer is disposed to go farther, and to regard the incipient *jus gentium* as having been, in fact, the custom of merchants. Without some general customs trade could not have gone on at all, and if they existed it was an obvious course for the Roman jurisdiction to adopt them. Sidgwick rightly notes in the same chapter the theoretical divergence between *jus naturae* and *jus gentium* on the point of slavery.

The mediæval section is remarkably good, although Henry Sidgwick's particular tastes and studies did not lie that way. Mediævalists, as well as ordinary historical students, will find profitable matter in the treatment of Italian and German autonomy with regard to the general political development of Europe. The contrast between Continental feudalism, leading first to wild particularism and then to a reaction towards absolute monarchy, and the stronger central government which saved England from despotism, by an apparently despotic but really popular system, is not in itself new, but is thoroughly well brought out.

England, nevertheless, had a narrow escape; we have been slow to realise how narrow it was. Mr. Maitland was the first, we believe, in his Rede lecture two years ago, to claim boldly for the common law and its traditions their due share in effectual resistance at the critical time. This point, though lightly touched on by Sidgwick, did not escape him; see his well weighed remarks on the unity of the common law and of Parliament (p. 312). The beginning of modern political history and constitutional doctrine is placed at the peace of Westphalia, and we do not think a better date could be found. We have some doubt on a matter of detail in the next stage. Blackstone is the normal representative of the doctrine accepted in the reign of George III. Sidgwick acquiesces in the current view of Montesquieu's influence on him, but we think that Blackstone's own practical consideration of Locke may have counted for more than is commonly supposed, and Montesquieu, whose work was still very recent when Blackstone wrote, for less. Although Blackstone was not, on the whole, an original thinker, there is no reason to assume that he never did any thinking for himself.

The reader is finally conducted with a sure hand through the modern development of constitutional and cabinet government to the prospect of federalism as the most important factor in the coming generation.

FREDERICK POLLOCK.

A CONTRIBUTION TO CALIFORNIAN GEOLOGY.

The Palaeontology and Stratigraphy of the Marine Pliocene and Pleistocene of San Pedro, California. By Ralph Arnold. Pp. 420; 37 plates. (California: Stanford University, 1903.)

THIS, the latest of the well-known "Contributions to Biology from the Hopkins Seaside Laboratory of the Leland Stanford Junior University" (reprinted from the *Memoirs* of the California Academy of Sciences, vol. iii.), forms a dissertation presented to the faculty in geology of the university for the degree of doctor of philosophy, and is by far the bulkiest of the thirty-one "Contributions" as yet published.

It may not, perhaps, contain matter apparently offering such brilliant results as some of its predecessors, but it yields to none of them in being a most sound and important contribution to the knowledge of a scarcely touched subject. Nor is it the outcome of some spasmodic effort of the moment, for Mr. Arnold began the work in the winter of 1886, and has paid several visits each year since to the fossil-bearing beds of San Pedro.

In the field work and in collecting the author had the assistance of his father and the further cooperation of numerous friends, principally of Dr. J. P. Smith, Dr. J. C. Branner, and, in the systematic work, of Mr. Wayland Vaughan and Dr. Dall.

The deposits investigated rest on raised and contorted Miocene shales, while a similar unconformity is evident between the Pliocenes and Pleistocenes themselves. All are successively overlain by alluvial soil with Kitchen-middens. In thickness these beds exceed any of the same age in this country, and attain in the Pleistocene to more than 1300 feet, and in the Pliocene to about 5000 feet.

In the first portion of the work the information concerning the various subdivisions is summarised, and lists of the several fossil contents are given. The faunal relations of the beds are of great interest. The fauna of the Pliocene strata is similar to that now living only a short distance off-shore from San Pedro, but probably in colder water than is found in-shore; it also contains 18·5 per cent. of species only found living further north, hence the climate was probably colder on the coast of California at the time of deposition than it is at the present day.

In the succeeding Pleistocene deposits the lower series reveal by their fossil-contents a change in climatic conditions towards tropical, while in the upper series semi-tropical conditions appear to have prevailed.

Great similarity is shown to exist between the later Tertiary and Pleistocene marine invertebrate fauna of Japan and that of the western coast of the United States, though the living faunas are not as closely related.

The second portion, or the "description of species," forms the bulk of the work, and occupies 276 pages, of which all but 12 deal with the Mollusca. The excessive preponderance of molluscan remains, indeed, is one of the most remarkable features connected with these beds. The diagnoses of the few new Anthozoa are by Mr. Wayland Vaughan, whilst to Dr. Dall the author acknowledges indebtedness in the identification of some of the Mollusca and for superintending the text relating to the Pyramidellidæ, which was prepared by Mr. Paul Bartsch.

In his classifications the author has wisely followed well-known text-books or memoirs, and though this course necessarily results in the nomenclature being in some places not quite of the latest description, it enables the work to be more readily followed than if some fresh arrangement had been adopted. One rectification we are glad to note in Mr. Bartsch's portion—Fleming's name, *Odostomia*, resumes its pride of place.

A useful bibliography forms the third part of the volume, albeit unduly extended to include works that might have been, rather than that were, actually referred to, and even to embrace all the papers of one writer because he was considerate enough to supply them, although a considerable number have no bearing whatever on the question. That the G. B. Sowerbys should have become mixed is not surprising, but "Sowerby, James, and De Carls, James" should have been avoided.

The thirty-seven plates, twenty-one of which relate to the fossils, are of that high quality which we have come naturally to expect in works of this class produced in the United States, and he who could find aught to cavil at in them must indeed be hard to please.

B. B. W.

PHYSIOLOGY AND ALCOHOL.

Elementary Physiology and Hygiene. By Prof. Buel P. Colton, M.A. Heath's Modern Science Series. Pp. viii+317. (London: D. C. Heath and Co.) Price 2*s.* 6*d.*

THIS book has obviously been written to supply the wants of the American schoolchild, and consequently

"the subject of *alcohol* has been treated very thoroughly and in full compliance with the laws of the various States."

"Throughout the book the effects of alcohol and other narcotics have been discussed in close connection with the accounts of the functions of the body."

"A number of authoritative quotations have been made, so that the pupil may know that the statements made are supported by the most eminent authorities of the world on these subjects."

The above quotations from the author's preface show that it has been a pleasure to him to comply in his book with the law enjoining that all text-books of physiology used in American State schools must contain a description of the effects of alcohol upon the body.

So thoroughly has this instruction been carried out that it appears on reading the book as if in many cases the very brief descriptions of the physiology of the different tissues had been written chiefly as introductions in order to make clear the dire effects of alcohol, which are subsequently described in each case.

There is a denunciation of alcohol in every chapter, and its ill effects upon every tissue in the body, from the bones to the brain, through the whole gamut of the muscles, blood, circulation, respiration, digestion and excretion, are specially described in words usually chosen from well-known authors; and then, as if feeling that this alone were not sufficient, the author adds a chapter, written in great part by himself, dealing entirely with alcohol and its disastrous effects upon the body.

Truly this book must be appalling reading to the American schoolchild whose parents may be in the habit of making even moderate use of alcoholic drinks, until time has eventually brought the convincing comfort that the parents do not suffer so badly as might have been expected from the descriptions of the text-book.

It is a pity that the picture is so overdrawn, both for the sake of the effect upon the mind of the child and the valuable reformation of the parent which might have been effected through the child.

It is most desirable that every adult in every country should know the evil results upon the system of over-indulgence in such a powerful drug as alcohol, but it is highly questionable whether any good result can follow the drawing of such lurid pictures as are found here for the perusal of boys and girls at school.

The style of the book is not beautified by the use of the English instead of the Latin plural, so producing such monstrosities as *pleuras, ganglions, ciliums, villuses,* and *papillas.* The author states that this has been done to avoid puzzling the student who has not "had Latin," appearing to forget that such words have become part of the language, and that it is a drastic procedure to coin many new and uncouth words to save his readers the labour of acquiring a knowledge of the Latin plural forms. This knowledge they ought already to possess at school before they have reached the stage of studying physiology and hygiene, unless school work is becoming very inverted and chaotic.

In addition to inventing new plurals, the author in his preface admits the manufacture of new words, again on the plea of simplicity, and further examples of this practice are to be found in the text, such as *aur-vent* and *vent-art* valves on p. 52.

The book contains a smattering of popular physiology and a very small amount of elementary hygiene, but it appears to the reviewer to be a volume which ought specially to attract temperance lecturers in search of "material" for their discourses.

Benjamin Moore.

A BOOK OF ENGLISH SPORTS.

English Sport. Edited by A. E. T. Watson. Pp. ix+361; illustrated. (London: Macmillan and Co., Ltd., 1903.) Price 12*s.* 6*d.* net.

IN this handsome volume, illustrated by a large number of exquisite coloured plates (many of which are photographs), the editor has managed to compress into a comparatively small size an interesting and accurate account of all the chief English sports. All the articles, each of which is written by a recognised authority on his special subject, have previously appeared in the *Badminton Magazine,* but since the series was compiled with a view to subsequent republication in book form, there is not that lack of connection and completeness—to say nothing of overlapping—which is sometimes noticeable in collections of this nature. To particularise the names of the different contributors would be unnecessary on the present occasion, but a glance at the table of contents will be sufficient to convince the reader that the editor has been especially fortunate in obtaining the cooperation of such a number of names well known in the sporting world.

To review in detail a work of this nature comes more within the province of journals devoted specially to field and other sports, and we shall therefore, while commending the volume to the best attention of those whom it more immediately concerns, content ourselves with a few brief references to points more or less intimately connected with natural history.

All lovers of British animals cannot fail to find much matter of interest in the article by Viscount Ebrington on hunting the wild red deer in Devon and Somerset, of which his lordship, in his capacity as master of the hunt, probably knows more than any man living. Those who read this article must be convinced what an excellent lesson in "nature teaching" is afforded by the cultivation of the power of minute observation essential on the part of all those concerned in discovering the whereabouts of the quarry. In the article on harriers ancient and modern by the late Earl of

Suffolk and Berkshire, reference is made to the now almost forgotten fact that no later than the first half of the last century many of these hounds—and we presume fox-hounds also—were whole-coloured, instead of being of the tripartite "hound-colour" with which we are now familiar. Reddish was the prevalent tint, with a tinge of brownish-grey along the back, so that the hound was very similar in colour to the hare of which it was in pursuit. This, of course, has an important bearing on the ancestral stock from which our modern hounds are derived, and tends to confirm the view of Bell as to the derivation of these animals from a bloodhound stock.

As the editor admits in his preface, some objection might legitimately be raised to the inclusion in the volume of an article by Lord Delamere on lion-shooting in East Africa, and of another by Lord Walsingham on Spanish ibex hunting, since if these are admitted it is somewhat difficult to see why big game shooting in general was not included. Taking, however, the facts as they are, we find some very interesting points in Lord Delamere's narrative—notably the statement that wart-hogs, when chased by lions to the deserted aard-vark holes, in which they often take up their abode, invariably enter backwards, so as to present their formidable tusks to an assailant. In the course of his account of a hunting trip to the haunts of the Spanish ibex, or wild goat, Lord Walsingham records many interesting points in connection with the fauna and flora of the districts traversed.

With this we take leave of an attractive volume which ought to occupy a handy position in the library of every British sportsman. R. L.

OUR BOOK SHELF.

Theoretical Mechanics. An Elementary Text-book. Second edition. By L. M. Hoskins. Pp. xi+456. (Published by the author, Stanford University, Cal., 1903.) Price 3 dollars.

WE have here a very clear and lucid exposition of the fundamental principles of mechanics, presented always with incisive logic, in a simple manner, and enforced and illustrated at frequent intervals by well selected examples.

The book is divided into three parts, of which the first deals with statics, and includes a chapter on gravitation and the attraction of spherical shells. The second part is concerned with the dynamics of a particle, and part iii. treats of the motions of systems of material particles and of rigid bodies.

The subject is treated mainly by analytical methods, an elementary knowledge of the calculus being assumed. But the vector nature of the subject is always kept prominently to the fore, and the vector significance of the various terms in the dynamical equations is brought well home to the student by ample illustrations and descriptions. The book opens with a special chapter on vectors, and vector equations are freely employed throughout, verging sometimes on the use of vector products, as, for instance, when establishing the relations which exist amongst the various quantities in the case of the transformation of axes in the instructive chapter on relative motion which concludes the volume, and which has been added since the first edition.

Attention is mainly confined to motion of translation in space, and to the general case of plane motion, general motion in three dimensions being only casually alluded to. This seems to us a wise arrangement, as, in the space available, it allows the treatment to be very full and complete.

The C.G.S., the poundal-pound, and the "engineers'" systems of units are all clearly explained. The author, however, seems to be under some misapprehension as to the unit of force in the engineers' system. He says this varies with the locality on account of the variation of gravitation, but that the system could be made dynamical by specifying the locality. In this country, at any rate, such specification is made, and the engineers' system is thus as strictly absolute as the C.G.S. or the poundal-pound systems.

Considering the importance of harmonic motion in its many applications, as in electricity, in problems on balancing, in harmonic analysis, &c., many readers would have welcomed a special chapter devoted to the subject, including some reference to rotating vectors.

In a treatise like the present, it would seem highly desirable that a short account of the experimental verification of fundamental laws should be given, and the student be directed to carry out the experiments personally in the laboratory. But there is little room for adverse criticism in this most excellent text-book, which is one of the best on the subject that has recently appeared, and cannot fail to give satisfaction wherever used.

Atlas des Erdmagnetismus für die Epochen 1600, 1700, 1780, 1842 *and* 1915. By Dr. H. Fritsche, Director emeritus des K.R. Observatoriums in Peking. (Riga: Müllerschen Buchdruckerei, 1903.)

THIS work consists of a series of charts of equal lines of magnetic declination, inclination, and horizontal force for the five epochs 1600, 1700, 1780, 1842 and 1915, calculated by the author with the assistance of the Gaussian theory.

In his introduction he discredits the accuracy of the charts of the epochs hitherto published by Hansteen, van Bemmelen, Sabine and others as being the results of observation only, many of such observations being defective, and the lines drawn without the help of any theoretical groundwork. There is a mistake here as regards Sabine's charts of the Arctic and Antarctic regions, as the Gaussian lines calculated for 1840 were largely used in their construction. Nevertheless, the author has spared no pains in his endeavour to replace what he condemns by something better, hence the present charts.

Considering the existing knowledge of terrestrial magnetism as regards the secular change of the magnetic elements, and our limited knowledge from observation of the conditions in the southern parts of the earth, the author appears to be somewhat premature in providing charts of inclination and force for the epochs 1600 and 1700, especially when so little was known of either element before the early years of the last century.

From the lengthened period during which the declination has been observed, the means exist for comparing the theoretical results of these calculated charts with good normal observations. Thus at Cape Town we find for the epochs 1842 and 1915 a difference in declination of $-1^{\circ}.5$ and $+2^{\circ}$ respectively, and at other well-known places similar differences.

Again, these charts indicate that the north magnetic pole moved in a south-easterly direction nearly 700 miles in the 315 years since 1600, some 93 miles of these being traversed between 1842 and 1915, whereas observations during the latter period indicate that the pole moved in a north-westerly direction. The south

magnetic pole is declared to have moved about 800 miles in a north-westerly direction between 1600 and 1780, then about 400 miles in a south-easterly direction between 1780 and 1915.

The remarkable results thus given in these charts can hardly be accepted until observation has done its work and provided a better basis of calculation than that at the disposal of their author.

The Wonderful Works of God. Pages from the Book of Nature. By J. Polkinghorn. Pp. iv+156; illustrated. (London: Society for Promoting Christian Knowledge, 1903.) Price 2s.

THE purport of the book, it is said, is to awaken an interest in the marvels of creation, and perhaps this might have been done without the introduction of quite so many "pious reflections." Be this as it may, the author might at least have taken care that all his statements were up to date, and at the same time have avoided the introduction of misleading illustrations. As an example of the former failing, we may refer to the statements (p. 29) that sponges are included in the Cœlenterata, and (p. 94) that a few birds probably hibernate (*vide* A. Newton, "Dictionary of Birds," p. 928). As regards the second point, we may direct attention to the figure on p. 29, in which the shell borne by a soldier-crab presents no resemblance to that of any mollusc with which we are acquainted. Although exception may be taken to the mode of treatment, the purport of the book is deserving of all commendation.

Riviera Nature Notes. Second edition. Pp. xv+402. (London: Bernard Quaritch, 1903.)

THIS volume will be a welcome addition to the library of everyone who is interested in the old-fashioned hobby of field natural history or its modern substitute of "nature-study." The first edition, which was published in 1898, was a delightful book, but it left much to be desired in the matter of paper, printing, illustrations, correction of misprints, and similar matters of general detail. In all these respects the present volume is quite a different book from its predecessor, and though a few misprints still survive, it is evident that no pains have been spared in producing a well printed book, the illustrations in which are quite works of art. The anonymous author states that he is a schoolmaster by profession, and that the book was written as a recreation, and with no intent to produce a scientific treatise. But those who have visited the shores of the Mediterranean will know that the fauna, the flora, and the folklore of this region possess an individuality of which no adequate impression can be conveyed by exact scientific descriptions, but of which a much better idea can be obtained from the descriptions and illustrations given by one who is evidently familiar with every nook and corner of the district. We cordially agree with the last words of the preface:—"But I may, perhaps, venture to plead that there are many recreations even less profitable than writing notes upon the Natural History of the Riviera."

The Square Circled. By P. O. P. Pp. 44. (Edinburgh: E. and S. Livingstone, 1903.)

MANY writers have given approximate geometrical constructions for straight lines equal in length to arcs of circles, and some of these are so simple that it seems a pity they are so rarely seen in text-books. This remark in no way applies to the constructions given in the present book. Most of the figures are very involved and complicated, containing between thirty and forty lines. If the methods really did lead to an exact and not merely an approximate construction for squaring the circle, the use of ruler and compasses would introduce errors far greater than those which would arise from taking even such a rough value for π as $3\frac{1}{7}$. It is a pity that the author before writing this book did not consult a mathematical friend. Had he done so he would have been told that his "V-shaped curve" is a portion of a cycloid, and he would not have issued the book in its present form.

The Garden Diary and Calendar of Nature. With Gardening Directions by Rose Kingsley and Preface by G. A. B. Dewar. Pp. x+Diary. (London: George Allen, 1904.)

A FEW nature and other notes, together with directions as to the month's work in the garden, precede the diary for each month. Every day throughout the year is provided with an appropriate poetical quotation and a space in which to record personal observations of nature in the garden and elsewhere. Altogether a pleasing compilation.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Oxford Science.

To the report of a lecture recently delivered in Oxford (NATURE, vol. lxix. p. 207) Prof. Perry appends a footnote in which he states that if he were to endow a professorship in some definite branch of science at Oxford, the authorities would appoint a man who never had done, and who never could be expected to do, any research work, and whose highest ambition would be to act zealously as the bursar of his college! As some of the readers of this report might regard this statement as being literally true, it is as well it should be contradicted. Of the fourteen full science professors at Oxford, only one is, or ever has been, a college bursar. In fact, nearly all the professors are eminent men, who by their research work have contributed in no small measure to the advancement of science. All are fellows of the Royal Society, and nearly all have served on its council.

Prof. Perry's statement that Oxford turns out very little research work of any kind is likewise unsupported by facts. As can be seen from the "Reports of University Institutions" (published by the Clarendon Press), the amount of research work done in Oxford is increasing every year. To take but a few instances, we find that, in 1902, workers in the department of physiology published eighteen original memoirs, those in the department of astronomy eleven, and those in the department of comparative anatomy ten memoirs, whilst from the Hope department of zoology two bulky volumes of collected researches have been published within the last few months. In fact, I challenge Prof. Perry to name a single professor, lecturer or demonstrator, in the departments of physiology, comparative anatomy, zoology, geology, botany, physics (electricity), astronomy or mineralogy, who is not engaged upon research at the present time, and who has not published original work during the last year or two. Again, many of the colleges are subsidising research by electing research fellows rather than fellows by examination. Of such fellows—all elected within the last few years—it will suffice to mention the names of Messrs. Arthur Evans and D. G. Hogarth, whose exploration work in Crete is known to all, and Messrs. Grenfell and Hunt, equally well known for their work in Egypt.

The statement that Oxford hates science does not seem to be borne out by the fact that, of the total yearly revenue of the university (as apart from the colleges), more than 10,000*l.*, or a seventh part of the whole, is devoted to the upkeep of the science departments and the payment of science readers and lecturers. Many of the colleges are no less liberal in their support of science and research. To

take a single instance, Magdalen College spends more than 5000*l.* a year upon science professorships, fellowships and scholarships, or a seventh part of its net revenue, and of the last twelve fellowships it has awarded, six have been for research. Also it keeps up a very efficient private laboratory, as, indeed, do five other colleges in the university.

Oxford, January 9. H. M. VERNON.

I THINK that others may interpret the footnote as Mr. Vernon does, and it is therefore my intention to express myself more clearly when the address is republished. Surely all Oxford science men know what I meant to say, and if so, they must know how difficult it is to say it without making two or three particular references. It is evident from other parts of my address that I certainly did not mean that most of the Oxford science professors neglect research. On the contrary, I know that the majority of them perform their duties well, including duties as to research, and they do this in an antipathetic atmosphere such as science professors elsewhere know nothing of. If I had the inclination to punish a scientific man and the power, I would appoint him to an Oxford science professorship.

Some of the most distinguished workers were listening to my address, and I know that they were not much annoyed when I expressed my opinion that, relatively to the position and wealth of Oxford, there is very little being done. We know the names of the Oxford men who are doing good research work in Oxford and elsewhere, and surely Mr. Vernon will not say that they form one-tenth of one per cent. of the number of living men who have been educated at Oxford. But I am not concerned with the easy standard which he is satisfied to apply. I was expressing what is a very general opinion, and one that is certainly my own. Also in saying that Oxford fears and hates natural science I was expressing a very general opinion. It is ridiculed by Mr Vernon, but he does not disprove it when he tells how Oxford trifles with science by the establishment of what are called science scholarships and fellowships and starved little laboratories.

Public opinion has been burked for many years by this grotesque fooling. Add to this that the majority of the dons throw ridicule upon natural science studies and create an atmosphere in which it is nearly as difficult for a man to do scientific work as it is for a mouse to live in an atmosphere of carbonic acid. An earnest student of natural science swims in a sea of troubles, and the university authorities in their love for him ornament him with a millstone of compulsory Greek as neck ornament. Surely this is something worse than trifling; it is torture. The torture is not so exquisite as what is applied to natural science in schools which are under Oxford influence, but it serves its purpose. JOHN PERRY.

An Undescribed Rudimentary Gill-plume in the Cray-fish.

I SHOULD be glad if you would allow me to place on record the discovery, by Miss Margery Moseley (daughter of my old friend, the late Prof. H. N. Moseley, of Oxford), in specimens of the common cray-fish (*Astacus fluviatilis*), of a pair of minute gill-plumes (right and left), belonging apparently to the somite of the first pair of maxillipedes. Miss Moseley discovered these new minute gill-plumes, independently, in the course of dissection of a series of "types" in the department of comparative anatomy at Oxford. Finding no description of them in the text-books, and that they were not recognised or admitted by the authorities, she sent her notes and drawings on the subject to me. The discovery has been confirmed at my request by Dr. Calman, who is engaged in work on the Crustacea at the Natural History Museum, and he expresses his astonishment (in a letter to me) that so important and (when once noted) so obvious an organ can have been overlooked by the many students who have carefully examined the cray-fish since Huxley made it one of his "types," and published his researches on the gills of the astacoid Crustacea.

The discovery is interesting, not only as a fact in the morphology of Crustacea, but as being a novelty in a subject treated with special attention by so skilled an observer as Huxley, and minutely examined by thousands of students and teachers during the last twenty years. Miss Moseley is preparing a description and drawings of the new gill-plumes for immediate publication.

January 15. E. RAY LANKESTER.

A Theory of the Cause of Atmospheric Electricity.

THE idea that the sun sends out a large amount of Becquerel rays has found considerable support in the scientific world, and has been used to explain a number of difficulties connected with cosmical physics, for example, the source of the sun's energy and comets' tails. There is still another old standing difficulty which it appears to be able to solve, viz. the permanent maintenance of the electrical field in the lower regions of the earth's atmosphere. If we take for granted that the sun continually emits Becquerel rays consisting of positive and negative electrons, one would expect the following to be the consequence. Some of the electrons which reach the earth's atmosphere will be absorbed—probably mainly by the water vapour and dust in the lower atmosphere—but according to Rutherford's experiments more positive than negative; thus we may expect a greater number of negative electrons to reach the surface, a corresponding number of positive electrons being held back by the air. We at once see a cause for the positive charge of the air and the corresponding negative charge on the surface. If there were no "dissipation" the result would be a continual charging up of the atmosphere or an ever increasing potential gradient above the earth's surface; but there is dissipation, and it counterbalances the tendency of the electrical field to increase. If we had a constant dissipation the result would be a maximum potential gradient in the daytime and a minimum in the night, for we must assume that more electrons reach the atmosphere in the day than in the night. But we know from Elster and Geitel's measurements that the dissipation reaches a maximum at midday; this will tend to reduce the maximum of potential gradient which would otherwise be reached about that time. This consideration agrees entirely with the fact, for Exner has described the daily variation of the potential gradient as "a simple daily period, distorted by a midday depression." With the fairly constant daily period of the entrance of electrons into the atmosphere, the main determining factor of the potential gradient will be the dissipation; thus we find a maximum potential gradient in the winter with a corresponding minimum dissipation. The relation between potential gradient and dissipation has been thoroughly investigated by Elster and Geitel, and they have found experimentally that "that which tends to reduce the dissipation tends to increase the potential gradient," which is just what one would expect from the theory. This theory appears to me to be able to account for a great many more of the problems of atmospheric electricity, but the above will show the general idea. GEORGE SIMPSON.

Projection of Imitation Spinthariscope Appearance.

WITH reference to Sir Oliver Lodge's letter in NATURE of last week (p. 247), might I venture to say that I exhibited to a large audience the nature of the effect seen in a spinthariscope in a lecture which I gave on radio-activity at the Cavendish Laboratory last term? My plan is somewhat similar to that suggested by one of Sir Oliver Lodge's sons, and consists of two black discs rotating in opposite directions in a mechanical slide. The discs have a large number of transparent spots, so that whenever two of these coincide a flash is produced on the screen. The resultant effect is the same as that seen in the spinthariscope. The coincidences can be arranged so as to be most numerous near the centre. J. B. B.

The Diminishing Size of the New Bishop's Ring around the Sun.

IN addition to the notes recently given in NATURE by Prof. Forel, Mr. Rotch and Mr. Backhouse concerning the new Bishop's Ring, I should like to direct attention to the steadily diminishing size of this ring.

Mr. Backhouse says in vol. lxvii. (p. 174) that the middle of this reddish ring in the summer of 1902 was 70° from the sun, but on December 21 it was only 40° from the sun.

The first measurements made by me were on January 9, 1903, when I found the faint reddish ring extending from between 25° and 30° to about 40° from the sun, the mean distance being about 33°. On January 20 several measurements made with an altazimuth instrument gave the mean distance of the middle of the red ring as 30° (see *Science*, N.S., vol. xvii. p. 150, January 23, 1903). On February 24, measured by an altazimuth instrument, the reddish glow extended from 26° to 31° from the sun, the mean being about 29°. On May 13 the average distance of the middle of the ring was by measurement roughly about 30°. On June 26 it was found to be about 26° from the sun. All these measurements were made at Blue Hill between 10 a.m. and 2 p.m., and the distance was measured from the sun vertically upward to the ring.

On September 1 Mr. Rotch, when on the summit of Mont Blanc, measured the distance of the ring from the sun, and found it to be between 20° and 25°, which would give a mean distance of about 23° (NATURE, vol. lxviii. p. 623).

On October 14 I again measured it at Blue Hill with a sextant, and found it extended out to 26°, which would give a mean distance of about 23°. A recent measurement by me on December 28 with an altazimuth instrument showed that it extended from about 16° to 24° from the sun, giving a mean distance of 20°.

Putting these measurements together, the following results are obtained:—

1902 Aug.	Dec.	1903 Jan.	Feb.	May	June	Sept.	Oct.	Dec.
70°	40°	32°	29°	30°	26°	23°	23°	20°

These results show a very rapid decrease in size at first, followed by a diminishing rate of decrease.

When I began my measurements I had not seen the letter of Mr. Backhouse, and did not see it until about a month ago. I anticipated that the ring would grow larger with time, reasoning that if the ring was a diffraction phenomenon, due to volcanic dust, the larger particles of dust would fall first to earth, leaving the smaller particles, and theoretically this ought to increase the size of the ring. I have been surprised to see the ring grow smaller. Perhaps it is because the whole of the particles causing it are getting nearer to the ground. Inside the very faint reddish ring described above, is a whitish glare which is visible to everyone, but I find that many people are unable to distinguish the reddish ring, which is very faint, and only distinguishable by anyone on the clearest days, and is most distinct when the sun itself is hidden by a cloud.

HENRY HELM CLAYTON.

Hyde Park, Mass., December 30, 1903.

Subjective Images.

WILL you kindly allow me to submit the following case for the consideration of your readers? I was reading a book one day in the open air, and the full light of a strong sun was shining on the printed page. After reading for about half an hour, I went over to a fountain, a few yards distant, in the shade of some trees. On a white marble slab attached to the fountain, there was an inscription, which I knew to be in jet black letters. To my surprise, the letters now appeared to my eye a rich emerald green. So brilliant and persistent was this green that I thought, for a time, that the colour had been really changed. After a few minutes, however, the green hue slowly faded away, and the letters appeared black as before.

The explanation that occurs to me for the moment is that the impression made on the retina by the different colours present in white light, lasts longer for some colours than for others, and that it lasts longest for the green. Thus the retina having been exposed for a considerable time to an intense white light, retained the impression of green after the impressions made by the other colours had faded away, and accordingly those portions of the retina on which the image of the black letters fell would still produce the sensation of green, while that sensation would be practically effaced for the remainder of the retina by the strong white light of the marble slab. It would be interesting, I think, if any of your readers could give evidence of a similar experience, or offer any better explanation of the phenomenon.

National Science Scholarships.

As a former student of the Royal College of Science and School of Mines, London, S.W., I was much struck by the hard working, studious demeanour of the national scholars I came into contact with at this excellent institution, and it seems to me that they are deserving of a better fate than being compelled to exist in London and to find many college necessaries out of 25*s*. per week, which I understand is only paid them during term time (p. 237). I am proud to be able to number several of these fine fellows among my intimate friends, whose mental calibre makes their companionship an acquisition; the miserable pittance doled out would seem hardly likely to attract such material, and seems to me only calculated, in many cases, to crush the element it professes to foster, and to turn out drudges for the general use and convenience of others possessing healthier digestions and a more extended knowledge of the world in general.

In this age of educational raving, when, apparently, it is assumed that the expenditure of large sums of money on the erection of colossal buildings is the surest way of building colossal minds, it makes one hesitate and wonder what education of any kind means.

Surely the object of scholarships should be two-fold, or more than two-fold, to make *men*, as well as *men of science*, and to educate in accuracy and truthfulness, and manliness also, and not to make mental and physical wrecks by ignoring earthly needs, yet the latter must result in many cases from such false economy. Either the scholarships should be made sound in every way or they should be abolished; the country would at any rate gain by a reasonable number of healthy minded citizens, which no nation can afford to despise in the race of life as it goes on to-day.

I think your suggestion of suitable halls and corporate life a good one; it is a need of the Royal College of Science, it is in fact, a need of all large colleges and universities drawing students from the various quarters of the Empire. The system of halls for a college should, in my opinion, be in miniature representative of the colleges of Cambridge and Oxford, a system which has probably assisted in maintaining the pre-eminence of these universities more than one is at first sight prepared to admit. Each unit belonging to the mother institution striving to obtain good men and fostering them by every encouragement to work for the hall they represent, let each hall have its cherished list of names of prizemen, and thus convert what, in a simple college not possessing such units, becomes a system of pacemaking into a healthy, manly, and sportsmanlike competition, in which the honour of the hall is at stake equally with that of the individual, where each will do his best work and be free from that tendency on the part of many high minded individuals to condemn themselves for entering into direct competition with less healthy, less capable men who nevertheless possess qualifications which make them respected by all to whom they are known, for the honour of the hall is a thing apart from self. Such a system would, I believe, tend to advance greatly the beloved institution which many others and myself regard as Alma Mater.

Bedford, January 14. W. H. PRETTY.

The Transvaal Technical Institute.

IN view of various unauthorised statements which have appeared from time to time in the public Press, the council of the Transvaal Technical Institute will be obliged if you will give publicity to the following particulars regarding the arrangements which have been made to meet the needs of this community and of South Africa generally in respect of technical education.

The classes for mining students which for seven years past have been held at Kimberley are being transferred to Johannesburg, and it is expected that some forty students will be in residence here at the beginning of next academic year (February).

To provide lecture rooms and laboratories for these students, the council of the Institute has taken over from Government the lease of the Boys' High School in Kerk Street, while a row of houses in Highfield Terrace will be furnished for boarding accommodation.

The council, aided by a committee at home, is making the necessary appointments to the teaching staff. Already

Prof. Hele Shaw, of Liverpool, has been appointed senior professor, and he will be in charge of the department of mechanical and electrical engineering, with Prof. Orr, late of Kimberley, as assistant professor. The chair of mining engineering and the assistantship in that department have not yet been filled, but arrangements will soon be completed for the due carrying on of this department.

The courses at present provided by the Transvaal Technical Institute are those of the third and fourth years of the Cape mining curriculum arranged by the University of the Cape of Good Hope, but the council has under consideration the development of the Institute, so as not only to give a complete four years' mining course, but also to provide courses in other departments of engineering and technical education generally, and to provide post-graduate courses for mining engineers.

Evening classes in subjects bearing on certain trades and industries are already being carried on in Pretoria and in Johannesburg, and the council is preparing a scheme of technical instruction for mines employees and others which involves the early opening of evening and day classes along the line of Reef, and eventually in other parts of the Transvaal.

The council of the Institute has also under consideration the wider proposals recommended by the Commission on Technical Education, and it is intended that no undue delay shall intervene in the carrying out of these.

JOHN ROBINSON (Secretary).

Transvaal Technical Institute, Secretary's Office, Johannesburg, December 23, 1903.

The Quadrantid Meteor Shower of 1904.

THE evenings of January 2 and 3 were clear here, but the moon being full and near perigee, rendered invisible in the north-eastern sky all stars less bright than second magnitude. A brief watch before midnight on January 2 indicated a total absence of meteors, and it was not thought advisable to prolong observations on this night, as it had been previously determined by the writer that it was on the following night that the Quadrantid maximum would occur.

The calculated time of this maximum was January 3, 18h. G.M.T. On the same night there was an earlier, and what had been supposed would be a much weaker, maximum at 13h. Observations were therefore commenced here shortly after midnight, and it very soon became apparent that, notwithstanding the strong moonlight, shooting stars were unusually numerous. Between 12h. 5m. and 13h. (Dublin time) there were observed 17 meteors, of which 8 were as bright, or brighter, than first magnitude stars. They made their appearance at very considerable distances from the Quadrantid radiant, and, owing to the very limited number of fixed stars visible in that quarter of the sky, it was impossible to record the meteor-paths with accuracy, but several of the latter indicated a divergence from the region of Boötes, there being at the same time another probable centre of emanation near the tail stars of Ursa Major.

The advent of clouds from the south-east rendered observations impracticable or fruitless between 13h. and 14h. 15m., but during the first quarter of an hour succeeding this interruption 4 more meteors were seen, of which 2 were of first and the rest of second stellar magnitude. The early maximum of the night was now evidently declining, as in the next half hour but 3 shooting stars were visible, the two brightest of these being only of second magnitude. The two hours' interval between 15h. and 17h. was remarkable for its meteoric paucity, only 1 bright meteor equal to second magnitude having been observed during this period at 15h. 30m., though the sky was very clear; and the watch would very probably have been abandoned after 15h. but for the maximum expected some hours later. This anticipation of a recrudescence of the phenomenon was fully realised, for between 17h. and 17h. 30m. 10 meteors were observed (half of them of first magnitude), although two-thirds of the eastern sky had by this time become covered with light clouds. The meteors radiated in all directions from a region very evidently situated in the north of Boötes. In the next ten minutes 2 more Quadrantids were observed, although the clouded area had by this time increased to five-sixths. Observations were discontinued at 17h. 40m. The meteors had a fairly rapid motion, and were slightly red in colour. Their paths ranged from 10° to 20° in length. The excessive moonlight must have detracted considerably from the splendour of the present display, but, even as it was, the meteoric rate during the shower's activity was much higher on the night of January 3 than on the corresponding night in 1903.

Dublin, January 13. JOHN R. HENRY.

M. Blondlot's n-Ray Experiments.

IT would be interesting to know whether anyone has succeeded in confirming the above, as described in your columns and elsewhere.

Personally, I have repeated most of M. Blondlot's experiments, but I have not been able to discern the slightest trace of any of the remarkable phenomena that he describes. This is also the case with Mr. J. C. M. Stanton and Mr. R. C. Pierce, who have assisted me in the investigations.

In order to get away from personal physiological idiosyncrasies we have also applied delicate photographic methods of observation, but without result, and as a general conclusion I am inclined to think that M. Blondlot's observations must be due, not to physical, but to physiological processes, and further, that these are not operative in the case of all persons.

Perhaps others may have tried the experiments and may have met with greater success.

Phosphorescence of Photographic Plates.

SOME time ago when developing an X-ray photograph I observed the effect noticed by your correspondent in your last issue. Very little of the silver salt had been affected, and the plate, after development, when put into alum solution lit up as described. I have often watched for the same effect since with ordinary negatives; sometimes there is phosphorescence, sometimes not. Apparently a fairly long development with the pyro soda is necessary. Not only the plate itself, but the used developer will give the phosphorescence with alum solution. Dilute sulphuric acid may be used instead of the alum. Quinine sulphate or hydrochloride does not light up when the used developer is added, but will do so if a few drops of sulphuric acid are subsequently introduced. Printing out paper may sometimes be successfully used instead of the plate, or the experiment may be still more easily made by mixing potassium bromide and silver nitrate solutions in dim gaslight, decanting, and shaking up the resulting silver bromide with pyro soda. A red liquid results which gives the lighting up effect when poured into alum solution or dilute sulphuric acid.

BIRD-LIFE IN WALES.[1]

ALTHOUGH the writings of Messrs. Murray Mathew, Cambridge Phillips and others have made us more familiar with the avifauna of southern Wales than we are with that of some other parts of that country, Mr. Walpole-Bond's description of the bird-life of a part of the district is not any the less welcome and instructive. For he enters very fully into the nesting habits and comparative abundance or scarcity of the birds in a way that is only possible to a good climber, indifferent to weather, who is able to devote every day wholly to the pursuit of his favourite study. The wild Wales of this book seems to lie, in the main, in part of the county of Brecon, although Pembrokeshire and other districts are touched upon. Incidentally, Bucks, Kent, and Hampshire are mentioned.

[1] "Bird Life in Wild Wales." By J. A. Walpole-Bond. Illustrated with photographs by Oliver G. Pike. Pp. xv+283. (London: T. Fisher Unwin, 1903.) Price 7s. 6d.

Wild Wales is still, happily, a stronghold of the buzzard and the raven, both of which are still fairly common there (the author seems to have had the luck to see no less than three buzzards' nests with eggs in one day), and enjoy a certain amount of protection or at least toleration, while the sight of a fork-tailed kite even may still gladden the eye of the bird lover, and we read of six seen in the air together! The management of the attempt to protect the kite in Wales, in support of which some members of the British Ornithologists' Union (which should not be called the "British Ornithological Society") have subscribed liberally, was in 1903 placed in the author's hands. Accordingly, a valuable chapter gives us an account of a nesting haunt of the kite in that year. But the birds seem to have had bad luck, despite the watchful care of the author. In the nest he found the kite addled one egg and cracked the other accidentally. A visit to Tenby in the breeding season

FIG. 1.—Merlin's Eggs in Crow's Old Nest. (From "Bird Life in Wild Wales.")

supplies material for an account of the ordinary sea-fowl to be found breeding just then. The little wader which remained unidentified was probably an immature turnstone, for many non-breeding individuals of this species pass the summer on the coast of Wales. The explanation of the light coloured shag seen on May 27 is, perhaps, that these birds do not attain adult dress in their first year, and this was immature.

Other chapters deal with the birds to be seen "in the hills" and along the river, with well-known feathered outlaws and some of the rarer birds of Wales. But the buzzard and the raven are the favourites of the author (who, indeed, devotes a whole chapter to the latter), and his personal observations on the breeding habits of these two species would alone make this pleasant book a valuable addition to the literature of the subject. The fact of the peregrine breeding in Breconshire is here recorded for the first time, and the author was lucky enough to find a merlin's nest, the second only recorded in that district. Additional interest attaches to this nest from the fact that the birds had taken possession of an old crow's nest in a tree, a most unusual thing in this country, where the merlin usually deposits its eggs on the ground or on a ledge of rock. About half the volume is occupied by an account of the author's bird-nesting and general ornithological observations on the birds of his own neighbourhood (in the form of a diary) from March to July, 1902. From these interesting pages we can gain a very good idea of the avifauna of the district, in which, by the way, the very local woodlark is to be found breeding.

The author includes a chapter of rough notes on climbing, collecting, &c., with an appeal to landowners to preserve our rarer birds. May we venture to supplement this with a hope that he will set no more traps for marten-cats? For the marten is every bit as interesting a member of our native fauna as the buzzard or the peregrine, and it is getting *very, very* rare. The author, when writing about egg collecting, states that the dealer is the worst offender in this respect, "for he stops at nothing, and will take as many clutches of a good thing as he can find." This, we fear, is quite as true of some collectors, and we must protest against the inference that the collector in general is one bit less to blame than the dealer. The collector stands in the place of "receiver," and whether or not it is true that the thief would not exist without the receiver, it is certainly true that the dealer would not exist without the collector.

As to the unsafety of "generalising" in observations all will agree. It is, perhaps, unsafe to generalise on such a subject as whether or no the curlew "seldom, if ever," lays less than four eggs. For in the case of ground-building birds, especially, the question whether a crow has visited the nest always comes in; but we have twice found three incubated eggs in a curlew's nest. If the missel thrush has usually ceased to sing in South Wales by April 15, its habit is very different in some other parts of Wales, where it may be heard well on into May. In Oxfordshire we have heard it in June. It may be pointed out with reference to the distribution of the garden warbler (p. 211) that it is common in Merionethshire, and not uncommon in parts of Carnarvonshire.

These charming pages are all the more refreshing reading because the author is evidently more accustomed to scaling crags and climbing "stiff" trees than to the making of books. All the same, a little more method in the arrangement would have husbanded space by avoiding repetition. For instance, the events of some March days detailed in the third chapter are repeated, with slight verbal variations, in the fifth, and in another place we notice that a note descriptive of bird-life recurs. The author thinks waterhen a better name than moorhen, "as one would no more expect to find one on a moor than a grouse in the river." But it may be pointed out that "moor" is an old English name for a wet meadow, and a "moorish" place is a wet place, so that moorhen was an appropriate English name for the bird long before English people had so much as heard of grouse moors.

The work is profusely illustrated with photographs of nests and bird haunts by Mr. O. G. Pike, the excellence of whose work is too well known to need further comment here. But we may direct attention especially to the clearness of the details of the sparrow-hawk's nest, the wool in the lining of the raven's nest, and the beautiful roundness of the pheasant's eggs. We do not remember to have seen a photograph of a woodlark's nest previously.

O. V. APLIN.

EARTH-MOVEMENTS IN THE BAY OF NAPLES.[1]

IN spite of the prolonged discussions on the question of changes in the relative level of land and sea in connection with the Temple of Serapis[2] at Pozzuoli, yet much remained unknown with respect to the movements of the Italian coast which it was surmised must have taken place since Roman times. An exclusive study of the columns of this building is insufficient to indicate the Roman sea-level relative to the land, for although the lowest portion of the columns, now below sea-level, was obviously above it, we cannot determine to what extent. Neither can we conjecture the size of the area affected by the movements; indeed, by the undue prominence which has been almost universally accorded to the Serapis phenomena in geological treatises, many authorities, among whom was Prof. Suess, were led to the conclusion that the phenomena were strictly local and almost confined to the Bays of Baia and Pozzuoli, in short, to the country immediately surrounding Monte Nuovo.

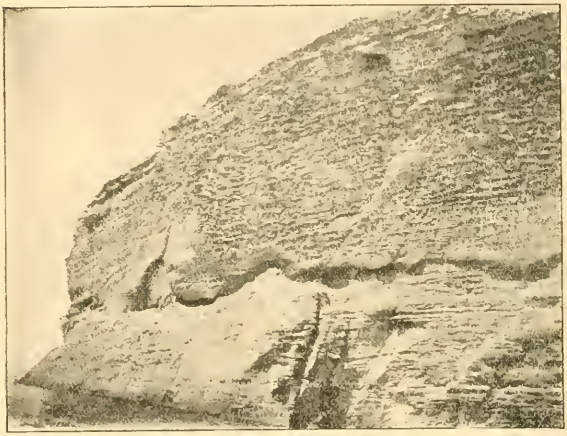

FIG. 1.—The Upper Groove of Erosion on Tufa Cliffs of Nisida.

Note the difference of the texture of the surface below the upper erosion line, which has been preserved by submergence, and that above, which has been weathered

It was with the object of collecting facts for the elucidation of these points, that we undertook the work of surveying and describing the little-known remains of Roman constructions which are so numerous around the Bay of Naples. Some of them are still standing on the present water-line, while some are awash and some deep beneath the surface: and from localities furthest from Monte Nuovo, we obtained evidence of earth-movements not less great than from localities nearer the mountain; thereby confirming our conjecture, as to the movement of the land spreading over a more considerable area than had been supposed at first.

At many points on the coast (Fig. 1), and especially in the limestone cliffs of Capri, the observer may note a clearly marked line of grooves and holes at a height varying from 23 feet to 12 feet above the present sea-level. This line, which presents the same appearance as one which traverses the rock face along the present water-line, is undoubtedly due to the same cause, namely, the eroding action of the surface of the sea. The upper marks of erosion correspond in height with the highest Lithodomus borings in the columns of the Temple of Serapis, thus showing that the entire Bay of Naples took part in the movement of the subsidence and subsequent elevation of the temple, and, as evidence of the same sort is to be found forty miles north at Gæta, and probably on the promontory of Mt. Circello as well, if atmospheric weathering has not obliterated the traces of marine erosion, the same alteration of land-level must have affected a large extent of the Mediterranean sea-board.

The changes of level have been deemed by some to be due to periodic changes in the level of the ocean. We are unable to accept this view, for we should expect the oscillations of the water-level to be of a regular and tide-like nature, as Niccolini, the eminent exponent of the theory, must himself have imagined, for the curve illustrative of his theory of marine phases is essentially a tidal curve, but the marks of erosion indicate spasmodic movements, changes of level during relatively short periods alternating with prolonged periods of rest. Another point against the theory of the change of sea-level is that the line of erosion, though continuous, varies in height; for instance, at the east end of Capri it is 10 feet higher than at the west, and smaller variations have been noted elsewhere. These facts are more reasonably accounted for by a theory of change of land-level, rendering inequalities in the oscillatory movement natural, than by a theory involving changes in the level of the sea.

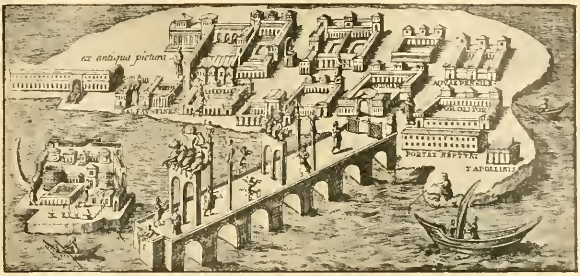
Interesting as it is to search for the traces of her handiwork that nature leaves in her own domain of rocks and cliffs, yet we confess to an interest not less keen in seeking out those she has left on the handiwork of man, on the remains of the Roman buildings by the sea. Massive piles of masonry and concrete, once part of some noble building, have been roughened by the never ceasing onslaught of the waves to the semblance of the brown rocks upon which they stand; and it is only possible to distinguish between the natural and the artificial on calm days, when they can be seen through the clear water.

It is the accumulated evidence furnished by these water-worn ruins that gives so strong a confirmation of our theory that, notwithstanding the oscillatory land-movement indicated by the upper erosion line before mentioned, the present land-level is far below the Roman land-level—how far we cannot exactly say, but we believe that the approximate figure of 17 feet will not be found to be very wide of the mark.

[1] The author's papers here summarised are:—"On the Possibility of Obtaining more Reliable Measurements of the Changes of the Land-level of the Phlegræan Fields (*Scottish Geographical Magazine*, October, 1900). "Earth-movements in the Bay of Naples" (*Geographical Journal*, August and September, 1903) "The Submerged Greek and Roman Foreshore near Naples" (*Archaeologia*, vol. lviii. pp. 1–62, figs. 1–29, plates xlv.–li., 1903). A few copies of the two last papers, reprinted with corrections, have been issued under the title "Contributions to the Study of Earth Movements."

[2] *Macellum*, or market-place, would be a more correct name for the building than "Temple of Serapis."

The evidence is of the most diverse description; masses of concrete or of Roman brickwork may be seen under water, so disposed that they show the ground-plans of the buildings they once supported; stairways with steps several feet below water are cut in the rock of caves, the walls of which still show traces of a stucco covering even where they are submerged; a drain which runs several feet below the surface, in a sea-side palace of Tiberius; artificial tunnels or *cuniculi* entirely submerged; these are but few among many other facts which have been a puzzle to antiquarians, and can be accounted for by the theory that the Roman land-level was about 17 feet higher than the present.



Pausanias Island.

Fig. .—The Breakwater of Puteoli, after a Roman Picture.

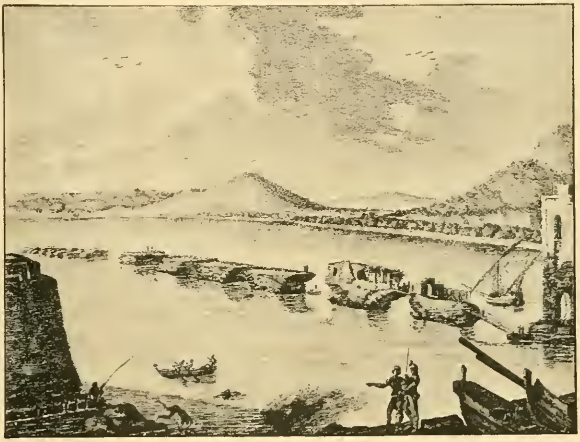


Fig. .—The Breakwater of Puteoli, after an eighteenth century drawing.

By the same theory we can explain why the malarious Lago d'Agnano was not mentioned by Roman writers, for it would not have been in existence with the land at the higher level; the present unhealthiness of the low-lying plain of Pæstum, once the site of a flourishing Greek colony, is also explained; then the Pool of Baiæ, mentioned by classical writers, and an island off Dicæarchia, described by Pausanias (Fig. 2), that have apparently vanished, we find by this theory to have been carried down by the land as it sank so that they are now covered by the sea; and finally the Roman fresco representing the famous breakwater of Puteoli Harbour (Fig. 2), which shows us the arches that join the piers or *pilae*, with the springing of the arches well above the water, is of the breakwater as the Romans saw it; nowadays the springing of the arches is submerged (Fig. 3).

These researches have thrown a new light on a point of controversy among scholars, namely, the question as to the exact site of the ancient Greek colony of Palæpolis, the mother-town of Neapolis, the present Naples. This ancient town was supposed by some authorities to have stood where Naples now is, by others to have been further inland towards Aversa. Following up our hypothesis that the shore was higher by nearly 17 feet than it is now, there would be a stretch of land extending nearly half a mile out to sea at the base of the cliffs of the promontory of Posilipo; it is here, where the ruins now under water attest to the existence of numerous buildings grouped round the Gaiola rocks, that we would place Palæpolis. Close by under the lee of this extended foreshore we discovered the defensive works of an ancient harbour, and we found many traces of an ancient coast road, also submerged, which ran along the foot of the cliffs and by tunnels through some of the little headlands on the eastern side of Posilipo (Fig. 4). This road gave an easy means of communication with the neighbouring colonies, and the many proofs we have found of its existence, as well as the geographical situation of the southern extremity of Posilipo, which was pre-eminently adapted to the conditions of Greek colony life, have emboldened us to believe that here, beneath the foundations of the later Roman edifices, the site of the vanished town is to be sought.

Fig. 4.—Ancient tunnel through Headland of the Villa Luisa, Posilipo. (After an oil painting by Mrs. Holcombe Ingleby.)

R. T. Günther.

THE ELASTIC LIMIT OF METALS.

COMMON SENSE, as Lebasteur has remarked, prevents us from denying the existence of a limit of elasticity in metals. It is true that the smallest load on a test-piece will cause a slight permanent set. Nevertheless, such structures as iron railway bridges retain their shape, and if a piece of metal is subjected to a small stress many times in succession, recovery after each application becomes almost perfect. What, then, is the elastic limit? The Commission des Méthodes d'Essai of 1894 announced that it is necessary to recognise three such limits:—

(1) The theoretical limit of elasticity or the maximum stress which does not produce a permanent strain (of more than a certain small amount).
